8 ABSTRACT: Climate models and observations robustly agree that Earth's clear-sky longwave
9 feedback has a value of about $-2 \text{ W m}^{-2} \text{ K}^{-1}$, suggesting that this feedback can be estimated
10 from first principles. In this study, we derive an analytic model for Earth's clear-sky longwave
11 feedback. Our approach uses a novel spectral decomposition that splits the feedback into four
12 components: a surface Planck feedback, and three atmospheric feedbacks from CO_2 , H_2O , and the
13 H_2O continuum. We obtain analytic expressions for each of these terms, and the model can also be
14 framed in terms of Simpson's Law and deviations therefrom. We validate the model by comparing
15 it against line-by-line radiative transfer calculations across a wide range of climates. Additionally,
16 the model qualitatively matches the spatial feedback maps of a comprehensive climate model. For
17 present-day Earth, our analysis shows that the clear-sky longwave feedback is dominated by the
18 surface in the global mean and in the dry subtropics; meanwhile, atmospheric feedbacks from CO_2
19 and H_2O become important in the inner tropics. Together, these results show that a spectral view
20 of Earth's clear-sky longwave feedback elucidates not only its global-mean magnitude, but also its
21 spatial pattern and its state-dependence across past and future climates.

22 SIGNIFICANCE STATEMENT: The climate feedback determines how much our planet warms
23 due to changes in radiative forcing. For more than 50 years scientists have been predicting this
24 feedback using complex numerical models. Except for cloud effects the numerical models largely
25 agree, lending confidence to global warming predictions, but nobody has yet derived the feedback
26 from simpler considerations. We show that Earth’s clearsky longwave feedback can be estimated
27 using only pen and paper. Our results confirm that numerical climate models get the right number
28 for the right reasons, and allow us to explain regional and state variations of Earth’s climate
29 feedback. These variations are difficult to understand solely from numerical models but are crucial
30 for past and future climates.

31 1. Introduction

32 Earth’s climate sensitivity is a crucial factor in understanding and predicting climate change.
33 While uncertainty in climate sensitivity is dominated by cloud feedbacks, the magnitude of climate
34 sensitivity is largely set by the clear-sky longwave feedback, λ_{LW} . Early studies estimated λ_{LW}
35 to be -2.2 - $2.3 \text{ W m}^{-2} \text{ K}^{-1}$ (Manabe and Wetherald 1967; Budyko 1969). These estimates were
36 impressively close to the current best estimates from climate models and observations, which agree
37 on a fairly narrow range for λ_{LW} of about -1.8 to $-2.2 \text{ W m}^{-2} \text{ K}^{-1}$ (Andrews et al. 2012; Chung et al.
38 2010; Kluft et al. 2019; Zhang et al. 2020; Zelinka et al. 2020). By contrast, the recent Sherwood
39 et al. (2020) assessment estimated the total cloud feedback to be both smaller in magnitude and
40 less certain at $+0.45 \pm 0.33 \text{ W m}^{-2} \text{ K}^{-1}$.

41 The robustness of the clear-sky longwave feedback suggests that one should be able to understand
42 and describe its governing physics in fairly simple form. A simple model for λ_{LW} would provide
43 definitive support for the value of $-2 \text{ W m}^{-2} \text{ K}^{-1}$ derived from observations and climate models.
44 It would also allow us to understand the state-dependence of λ_{LW} : at warm enough temperatures
45 Earth’s atmosphere transitions to a runaway state, in which λ_{LW} becomes zero or even changes
46 sign, but it is unclear how λ_{LW} varies between today’s value and the runaway limit. Similarly, there
47 is a long-standing interest in using paleoclimate proxies to constrain present-day climate sensitivity
48 (Tierney et al. 2020), but this effort suffers from uncertainty regarding the state-dependence of
49 climate feedbacks (Meraner et al. 2013; Bloch-Johnson et al. 2015). Finally, geographic variation
50 in feedbacks and their importance for the so-called pattern effect is an ongoing topic of research

51 (Armour et al. 2013; Andrews et al. 2015, 2018) , but if λ_{LW} has state-dependence then that
52 dependence should also influence the spatial pattern of λ_{LW} . For example, if the global-mean λ_{LW}
53 was different in past climates due to changes in the global-mean surface temperature, then present-
54 day λ_{LW} should show regional variation due to Earth’s surface temperature pattern, suggesting a
55 close link between state-dependence and spatial-dependence of λ_{LW} .

56 One of the earliest models for λ_{LW} was proposed by Simpson (1928a), who found that an
57 atmosphere that is optically thick due to water vapor would have a clear-sky longwave feedback
58 that is approximately zero, suggesting Earth should be in a runaway greenhouse. Although this
59 early model was abandoned by Simpson (1928b) as being overly simplistic, Ingram (2010) resolved
60 the Simpsonian “paradox” by separating out the parts of Earth’s outgoing radiation spectrum that
61 are optically thick due to water vapor (and for which λ_{LW} is approximately zero) from the optically
62 thin “window” region. Koll and Cronin (2018) subsequently quantified Ingram’s argument: using
63 fixed relative humidity (RH), single-column calculations they argued that for present-day Earth the
64 clear-sky longwave feedback is dominated by the surface:

$$\lambda_{LW} \approx \lambda_{\text{surf}}. \quad (1)$$

65 Here λ_{surf} is the surface Planck feedback, which is smaller than a blackbody’s feedback because
66 greenhouse gases block the surface’s emission outside the spectral window. Meanwhile, the
67 atmosphere itself contributes less to λ_{LW} in the present climate, and so to first order its contribution
68 can be ignored. It follows that atmospheric feedback terms which are often the focus of climate
69 model or observational analyses – the atmospheric component of the Planck feedback, the lapse-
70 rate feedback and the water vapor feedback – roughly cancel (Koll and Cronin 2018; Jeevanjee
71 et al. 2021a).

72 The match between λ_{LW} and the surface Planck feedback λ_{surf} in Equation 1 is not exact,
73 however. Follow-up work found that λ_{surf} only accounts for 50-90% of λ_{LW} in different regions,
74 with about 60% in the global mean (Raghuraman et al. 2019; Feng et al. 2022), implying a gap
75 in the argument of Koll and Cronin (2018). Similarly, Seeley and Jeevanjee (2021) showed that
76 in hot, high-CO₂ climates λ_{surf} becomes negligible yet λ_{LW} does not go to zero. As the surface
77 warms the atmosphere is still able to increase its emission to space in spectral regions that are
78 dominated by CO₂. This emission mostly comes from the upper atmosphere, and gives rise to a

79 spectral CO₂ “radiator fin” feedback. The existence of a CO₂ feedback means λ_{LW} must depend
80 on CO₂ concentration, and thus must have CO₂ state-dependence. Moreover, the CO₂ feedback
81 has to depend on the atmospheric lapse rate: if the atmosphere was isothermal with zero lapse
82 rate, CO₂’s forcing and feedback would both have to be zero, in line with previous work which
83 tried to quantify the dependence of CO₂ forcing on the lapse rate (Huang and Bani Shahabadi
84 2014; Dufresne et al. 2020), even if the details of the forcing mechanism are still disputed (Seeley
85 2018; Romps et al. 2022). So while the “surface-only” feedback picture from Koll and Cronin
86 (2018) gives a reasonable first-order approximation to λ_{LW} , more terms are needed to describe
87 λ_{LW} quantitatively.

88 In this study, we aim to derive a simple model of Earth’s feedback that can quantitatively
89 capture the magnitude of λ_{LW} as well as its state-dependence and regional variations. The model
90 decomposes λ_{LW} into the surface Planck feedback (λ_{surf}) plus three atmospheric terms: a CO₂
91 band feedback (λ_{CO_2}), a non-Simpsonian water vapor band feedback ($\lambda_{\text{H}_2\text{O}}$), and a destabilizing
92 water vapor continuum feedback (λ_{cnt}). Although these feedbacks are less familiar, they represent
93 the different substances through which Earth gives longwave radiation off to space, and how
94 each substance changes its emission under surface warming. As shown below, expressions can
95 be derived for each spectral feedback term starting from the basic equations of radiative transfer.
96 These expressions can be interpreted as a global-mean model for λ_{LW} or in terms of local feedbacks
97 (Feldl and Roe 2013; Armour et al. 2013; Bloch-Johnson et al. 2020). That is, each atmospheric
98 column is treated as an isolated 1D system whose longwave feedback depends on its local surface
99 temperature. We validate the model (and the utility of the spectral decomposition) by comparing
100 it against calculations with a line-by-line radiation code.

101 Our model of λ_{LW} is based on spectroscopic thinking and hence represents a different perspective
102 than the conventional decomposition which breaks the clear-sky longwave feedback into Planck,
103 Lapse-rate and Water Vapor feedbacks (e.g., Soden et al. 2008; Sherwood et al. 2020; Zelinka et al.
104 2020). The conventional decomposition has been an important tool for understanding λ_{LW} and for
105 diagnosing the physics governing outgoing longwave radiation in climate models. However, it also
106 obscures large cancellations between the atmospheric part of the Planck feedback, the Lapse-rate
107 feedback and the Water Vapor feedback (Held and Shell 2012; Koll and Cronin 2018; Jeevanjee
108 et al. 2021a). By obscuring these cancellations the conventional decomposition can give a false

109 impression of the uncertainty of climate models. The same cancellations also make it difficult
110 to understand the state-dependence of λ_{LW} – Planck, Lapse-rate and Water Vapor feedbacks all
111 increase in a warmer climate, but it is far from obvious how these changes add up to affect λ_{LW}
112 (Meraner et al. 2013). Building on previous discussions of spectral feedbacks (e.g., Huang et al.
113 2010, 2014; Koll and Cronin 2018; Pan and Huang 2018; Seeley and Jeevanjee 2021; Jeevanjee
114 et al. 2021a; Kluft et al. 2021; Feng et al. 2022), our goal in this paper is to show that the issues that
115 arise in the conventional decomposition can be resolved by viewing λ_{LW} in terms of its spectral
116 components instead.

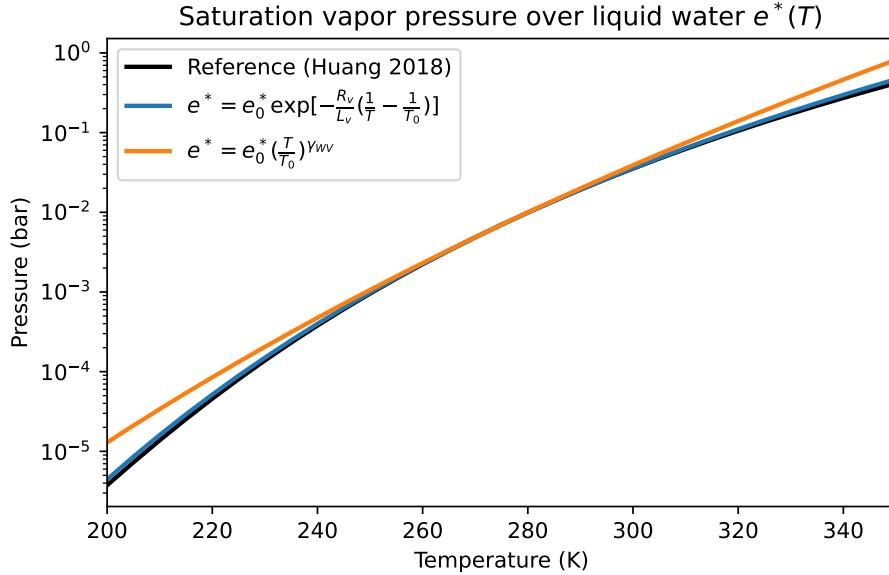

117 The layout of the rest of this paper is as follows. Section 2 discusses several preliminaries which
118 are necessary for the main derivations: an idealized Clausius-Clapeyron relation, an analytic
119 approximation for moist lapse rates and idealized band models for H₂O and CO₂ spectroscopy.
120 Section 3 lays out our spectral framework and introduces the emission-level approximation, our
121 spectral decomposition of λ_{LW} and a description of the numerical line-by-line calculations. Section
122 4 derives analytic expressions for Earth’s emission temperature in different parts of the spectrum,
123 which are then used in Section 5 to derive analytic feedbacks. Our expressions compare favorably
124 against the state-dependence of λ_{LW} from line-by-line calculations. Next, Section 6 uses these
125 results to understand the spatial pattern of Earth’s clear-sky longwave feedback. We generate
126 global maps of Earth’s clear-sky longwave feedback using a radiative kernel and climate model
127 data. We then show that our analytic expressions recover qualitatively similar feedback patterns,
128 which implies that the spatial pattern of λ_{LW} can be largely understood using our analytic model.
129 Breaking λ_{LW} up into surface versus atmospheric terms, we find that the surface dominates λ_{LW}
130 in the global-mean as well as in the dry subtropics, with a spatial pattern set by the pattern
131 of atmospheric relative humidity, while atmospheric feedbacks become significant in the inner
132 tropics, with spatial patterns that are set by regional lapse rate changes under warming. The
133 manuscript closes in Section 7 with a conclusion and broader discussion of the results.

134 2. Preliminaries

135 Our goal is to derive the longwave feedback of a cloud-free vertical column of atmosphere. The
136 column’s state can be specified using five parameters: T_s , γ_r , RH, q_{CO_2} and T_{strat} . Here T_s is the
137 surface temperature, $\gamma_r \equiv d \ln T / d \ln p$ is the temperature lapse rate, RH is the relative humidity,

138 q_{CO_2} is the CO_2 mass mixing ratio and T_{strat} is the stratospheric temperature. We idealize the state
 139 of the column by treating γ_{lr} , RH, and q_{CO_2} as vertically uniform; all are defined more precisely
 140 below. Similarly, we approximate the stratosphere as isothermal.

141 *a. Clausius-Clapeyron*

142 FIG. 1. Different approximations to the Clausius-Clapeyron relation. Black: fit based on experimental
 143 data (Huang 2018). Blue: the commonly-used quasi-exponential approximation. Orange: the power law
 144 approximation used in this work. The saturation vapor pressure is with respect to liquid water. In this plot
 145 (T_0, e_0^*) are set equal to the triple point values of H_2O , so $\gamma_{\text{wv}} = 19.8$.

146 The Clausius-Clapeyron relation governs the temperature-dependence of the saturation vapor
 147 pressure $e^*(T)$ and is an essential element of our analytic model. The Clausius-Clapeyron re-
 148 lation is often solved by ignoring the temperature-dependence of the latent heat of vaporization,
 149 $d \ln e^* / d \ln T = L_v(T) / (R_v T) \approx L_v(T_0) / (R_v T)$, which leads to the quasi-exponential approximation

$$e^* \approx e_0^*(T_0) \exp \left[-\frac{L_v(T_0)}{R_v} \left(\frac{1}{T} - \frac{1}{T_0} \right) \right]. \quad (2)$$

150 This quasi-exponential form does not lead to closed-form analytic expressions in the equations
 151 of radiative transfer, however, so we require a simpler form of the Clausius-Clapeyron rela-

152 tion. We obtain this by approximating the Clausius-Clapeyron relation further as $d \ln e^*/d \ln T =$
 153 $L_v(T)/(R_v T) \approx \text{const}$, which leads to a simple power law between temperature and saturation vapor
 154 pressure (Koll and Cronin 2019),

$$e^* \approx e_0^*(T_0) \left(\frac{T}{T_0} \right)^{\gamma_{\text{wv}}}, \quad (3)$$

155 where

$$\gamma_{\text{wv}} \equiv \frac{L_v(T_0)}{R_v T_0}. \quad (4)$$

156 Here T_0 is an arbitrary reference temperature around which we are approximating the saturation
 157 vapor pressure as a power law. We emphasize that T_0 is effectively a thermodynamic constant and
 158 does not change with surface warming. The non-dimensional power law exponent is large and
 159 reflects the steep rise of e^* with temperature; at Earth-like temperatures, $\gamma_{\text{wv}} \approx 20$. The fractional
 160 increase in saturation vapor pressure per unit warming is $d \ln e^*/dT = \gamma_{\text{wv}}/T \sim 7\%/K$, in line with
 161 other Clausius-Clapeyron approximations.

162 Figure 1 compares the approximations in Equations 2 and 3 against a fit based on experimental
 163 data (Huang 2018). Considering that a typical tropical atmospheric column spans the vertical
 164 temperature range 200 – 300 K, the quasi-exponential approximation is very accurate, whereas our
 165 power law approximation only matches to roughly a factor of two. Nevertheless, as shown below,
 166 this accuracy is good enough to match numerical calculations.

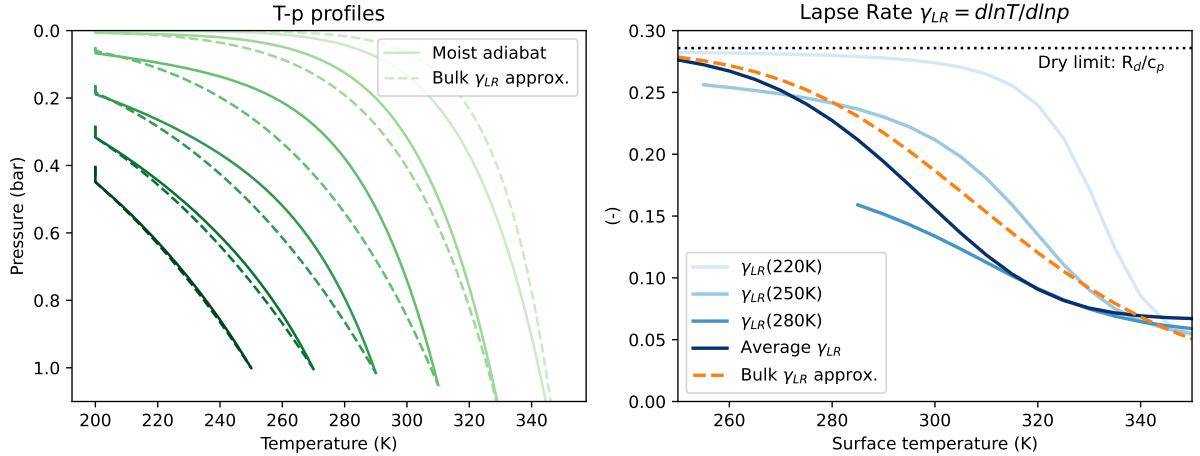

167 *b. Bulk moist lapse rate*

174 The vertical temperature-pressure profile of an atmospheric column can be specified via the
 175 lapse-rate exponent

$$\gamma_{\text{lr}} = d \ln T / d \ln p, \quad (5)$$

176 where p is pressure. For a dry adiabat the lapse rate exponent is vertically uniform, $\gamma_{\text{lr}} = R_d/c_p \approx$
 177 $2/7$. For a moist atmosphere γ_{lr} varies both as a function of temperature and pressure, but due
 178 to the latent heat release in a convecting parcel it is generally smaller than the dry lapse rate:
 179 $\gamma_{\text{lr}} \leq R_d/c_p$.

180 In order to obtain analytically tractable expressions we would like to treat γ_{lr} as constant in the
 181 vertical even for a moist column, so we diagnose a bulk γ_{lr} using the surface and tropopause values

168 FIG. 2. Moist adiabatic lapse rates versus our analytic approximation. Left: Pressure-Temperature profiles
 169 following a moist adiabat (solid) and following the bulk lapse rate approximation (dashed). Right: adiabatic lapse
 170 rate γ_{lr} numerically computed at three fixed temperature levels inside the troposphere (light blue), compared
 171 with the bulk approximation in Equation (9) (orange). Note that $\gamma_{lr}(T)$ is undefined if T is larger than the surface
 172 temperature T_s . The average γ_{lr} (dark blue) is a mass-weighted mean of all numerical lapse rates inside the
 173 troposphere, $1/(p_s - p_{tp}) \times \int_{p_{tp}}^{p_s} \gamma_{lr} dp$.

182 of (T, p) :

$$\gamma_{lr} \approx \frac{\ln(T_{tp}/T_s)}{\ln(p_{tp}/p_s)}. \quad (6)$$

183 Assuming that the tropopause temperature stays constant in response to surface temperature
 184 changes, in accord with the FAT/FiTt hypothesis (Hartmann and Larson 2002; Seeley et al.
 185 2019), then all that is needed is an expression for how p_{tp} depends on T_s . We can derive such an
 186 expression by first obtaining an expression for the tropopause height z_{tp} , following Romps (2016).
 187 From MSE conservation along an undilute moist adiabat between the surface and tropopause,

$$z_{tp} \approx \frac{1}{g} (c_p(T_s - T_{tp}) + L_v q_s^*), \quad (7)$$

188 where q_s^* is the mass mixing ratio of water at saturation, q^* , evaluated at the surface and we neglect
 189 q^* at the tropopause. p_{tp} can then be obtained as

$$p_{tp} = p_s e^{-z_{tp}/H}, \quad (8)$$

190 where H is the scale height of pressure ($= \frac{R_d T_{av}}{g}$) and $T_{av} \equiv (T_s + T_{tp})/2$. Plugging this into (6) yields

$$\gamma_{lr} \approx \frac{R_d T_{av} \ln(T_s/T_{tp})}{c_p (T_s - T_{tp}) + L_v q_s^*}. \quad (9)$$

191 One can show that Equation 9 correctly reduces to the dry lapse rate $\gamma_{lr} = R_d/c_p$ by setting $q_s^* = 0$
 192 and series expanding the logarithm, assuming $T_s - T_{tp} \ll T_{tp}$. In practice the latter assumption is
 193 not strictly true but the resulting deviation from the dry adiabat is small even for a 100 K difference
 194 between surface and tropopause.

195 According to the bulk approximation, γ_{lr} is constant in the vertical and varies only in response to
 196 climatic changes (e.g., changes in surface temperature). One can then integrate Equation 5 to solve
 197 for the column's temperature-pressure profile. This leads to a power law similar to a dry adiabat,

$$T(p) = T_s \left(\frac{p}{p_s} \right)^{\gamma_{lr}(T_s)}, \quad (10)$$

198 where the only difference to a dry adiabat is that now the lapse rate depends on surface temperature.

199 Figure 2 (left) compares profiles based on Equation 10 to moist adiabatic profiles. The moist
 200 adiabats are obtained by numerically integrating a generalized form of the moist adiabat which
 201 does not approximate water vapor as a dilute substance and thus remains valid at high temperatures
 202 (Ding and Pierrehumbert 2016). In all cases, the tropopause temperature is assumed to be fixed
 203 and equal to $T_{strat} = 200$ K. The analytic profiles given by Equation 10 produce a reasonable fit
 204 to the moist adiabats, though at surface temperatures below 340 K they produce slightly colder
 205 tropospheres. The tropopause pressure is accurately reproduced, as the analytic profiles always
 206 reach the tropopause at roughly the same point as the moist adiabats.

207 Figure 2 (right) compares the T_s -dependence of γ_{lr} . First, the moist adiabatic $T(p)$ profiles
 208 shown in Figure 2 (left) are used to numerically compute γ_{LR} at individual levels of the tropo-
 209 sphere. Because our bulk expression for γ_{LR} only depends on temperature, and not pressure,
 210 the moist adiabatic values of γ_{LR} are similarly shown at fixed temperature levels. Additionally,
 211 for each adiabatic $T(p)$ profile we compute the average moist lapse rate using a mass-weighted
 212 mean, $1/(p_s - p_{tp}) \times \int_{p_{tp}}^{p_s} \gamma_{lr} dp$. Figure 2 shows that our analytic approximation captures the T_s -
 213 dependence of the average moist lapse rate relatively well, though this general agreement can
 214 obscure significant differences at individual levels. For example, our analytic approximation of

215 γ_{r} deviates by more than a factor of two from the moist-adiabatic γ_{r} at the $T = 220$ K level. We
 216 will show below that these details of atmospheric lapse rates do not have a major impact on Earth’s
 217 longwave feedback at low surface temperatures, but they become increasingly important above
 218 ~ 300 K.

219 *c. H₂O and CO₂ spectroscopy*

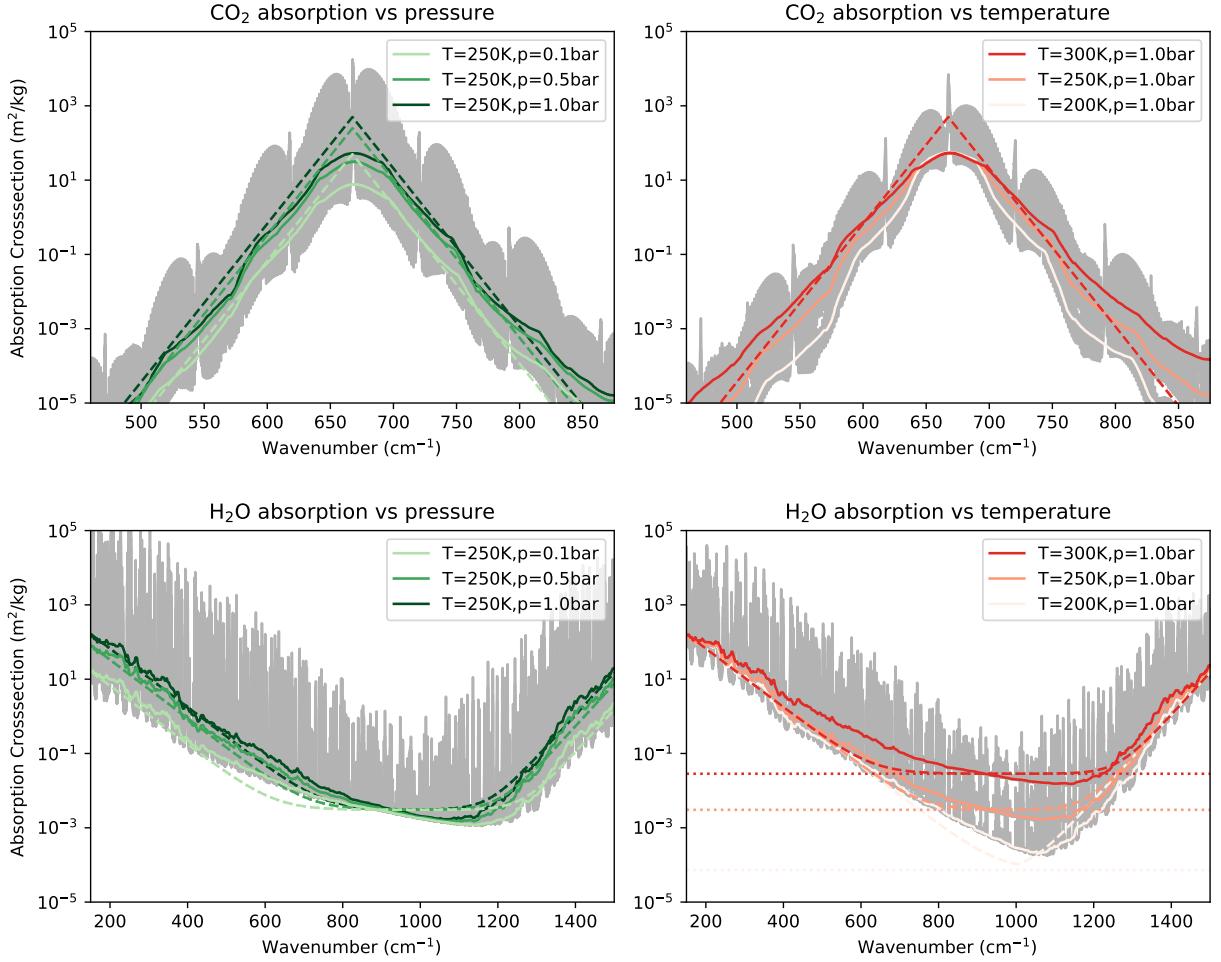

226 The third ingredient for our derivations is a model of H₂O and CO₂ spectroscopy. We follow
 227 previous studies and model the absorption cross-sections of H₂O and CO₂ as log-linear band shapes.
 228 Despite the simplicity of these models, they are able to explain numerous features of Earth’s climate,
 229 including the logarithmic nature of CO₂ forcing, the temperature-dependence of Earth’s surface
 230 feedback and the vertical structure of radiative cooling (Crisp et al. 1986; Pierrehumbert 2010;
 231 Wilson and Gea-Banacloche 2012; Koll and Cronin 2018; Jeevanjee and Fueglistaler 2020; Roms
 232 et al. 2022). Because we explore feedbacks over a wide range of temperatures, we additionally
 233 need to account for the H₂O continuum. We do so by approximating the continuum as a grey
 234 absorber.

235 For CO₂, the absorption cross-section is

$$\kappa_{\text{CO}_2} = \kappa_0 \left(\frac{p}{p_0} \right) \exp \left(- \frac{|\nu - \nu_0|}{l_\nu} \right), \quad (11)$$

236 where κ_0 is the absorption cross-section in the center of the band, p_0 is a reference pressure, ν is
 237 wavenumber, ν_0 the wavenumber of the center of the band and l_ν the decay rate of the absorption
 238 cross-section in wavenumber space. Previous work fit these parameters to the CO₂ absorption
 239 spectrum at a reference pressure of $p_0 = 0.1$ bar (Jeevanjee et al. 2021b). Because the choice of
 240 reference pressure is arbitrary, we here rescale the fits to the dry surface pressure in our calculations
 241 (i.e., the surface pressure excluding the contribution of water vapor), $p_0 = 1$ bar. The resulting
 242 values are $\kappa_0 = 500$ m²/kg, $\nu_0 = 667.5$ cm⁻¹ and $l_\nu = 10.2$ cm⁻¹.

243 H₂O band absorption can similarly be modeled using a log-linear shape, though one has to account
 244 for the fact that H₂O has two bands which are relevant for Earth’s longwave feedback. The rotation
 245 band determines H₂O absorption at wavenumbers less than 1000 cm⁻¹ and the vibration-rotation

220 FIG. 3. Idealized band models compared against the absorption cross-sections of CO₂ (top row) and H₂O
 221 (bottom). Grey envelopes show cross-sections computed at line-by-line spectral resolution, solid lines are the
 222 cross-sections smoothed by a median filter with width 25 cm⁻¹. Dashed lines are the band models for CO₂ and
 223 H₂O bands (the sum of line and continuum absorption), while dotted lines show the grey H₂O continuum model
 224 only. The CO₂ band model assumes the absorption cross-section is independent of temperature, so only one
 225 dashed line is shown in the top right.

246 band at wavenumbers larger than 1000 cm⁻¹. We model these two bands as

$$\kappa_{\text{H}_2\text{O},\text{line}} = \left(\frac{p}{p_0}\right) \max \left[\kappa_{\text{rot}} \exp\left(-\frac{|\nu - \nu_{\text{rot}}|}{l_{\text{rot}}}\right), \kappa_{\nu-r} \exp\left(-\frac{|\nu - \nu_{\nu-r}|}{l_{\nu-r}}\right) \right]. \quad (12)$$

247 The first term in the $\max(\dots)$ expression represents the rotation band, which dominates at low
 248 wavenumbers, while the second term represents the vibration-rotation band at high wavenumbers.
 249 The factor p/p_0 in front of both H₂O and CO₂ cross-sections reflects pressure broadening: under
 250 present-Earth conditions CO₂ and H₂O absorption lines become wider due to collisions of those
 251 molecules with the background air (N₂ or O₂). This has the overall effect that both gases become
 252 more efficient absorbers at higher pressure.

253 In contrast to the CO₂ and H₂O bands, the H₂O continuum is dominated by self broadening so the
 254 continuum cross-section is independent of pressure and instead scales as $\propto e = \text{RH}e^*$. Although
 255 continuum absorption is not uniform with respect to wavenumber, its spectral dependence is
 256 significantly weaker than the H₂O or CO₂ bands. We therefore approximate the continuum as a
 257 grey absorber and write

$$\kappa_{\text{H}_2\text{O},\text{cnt}} = \kappa_{\text{cnt}} \text{RH} \frac{e^*(T)}{e_0^*} \left(\frac{T}{T_0} \right)^{-a}, \quad (13)$$

258 where the dimensionless exponent a captures the direct temperature-dependence which acts to
 259 weaken the continuum (Pierrehumbert 2010). The total H₂O cross-section is the sum of line and
 260 continuum absorption, $\kappa_{\text{H}_2\text{O}} = \kappa_{\text{H}_2\text{O},\text{line}} + \kappa_{\text{H}_2\text{O},\text{cnt}}$. Because the line opacity decreases exponentially
 261 away from H₂O band centers, the total opacity becomes largely dominated by the continuum in the
 262 window region around $\sim 1000 \text{ cm}^{-1}$.

263 Our model of H₂O spectroscopy has eight parameters: κ_{rot} , l_{rot} , ν_{rot} , $\kappa_{\text{v-r}}$, $l_{\text{v-r}}$, $\nu_{\text{v-r}}$, κ_{cnt} ,
 264 a . We set $\nu_{\text{rot}} = 150 \text{ cm}^{-1}$ and $\nu_{\text{v-r}} = 1500 \text{ cm}^{-1}$, and fit the remaining parameters using the
 265 median-smoothed H₂O cross-sections shown in Figure 3 across the wavenumber range 150 cm^{-1}
 266 $\leq \nu \leq 1500 \text{ cm}^{-1}$. The results are sensitive to the smoothing procedure, that is whether one uses
 267 a geometric mean or a median. Because the average transmission across a spectral band tends to
 268 be dominated by the most optically thin frequencies (Pierrehumbert 2010), we use a median filter.
 269 To perform the fits we use the non-linear least-squares algorithm `scipy.optimize.curve_fit`,
 270 with a reference temperature of $T_0=300 \text{ K}$. We first fit the parameters κ_{rot} , l_{rot} , $\kappa_{\text{v-r}}$, $l_{\text{v-r}}$ to H₂O
 271 line opacities only, and then use these parameters to fit κ_{cnt} and a to H₂O cross-sections that
 272 include both line and continuum opacity. The resulting values are $\kappa_{\text{rot}} = 165 \text{ m}^2/\text{kg}$, $l_{\text{rot}} = 55 \text{ cm}^{-1}$,
 273 $\kappa_{\text{v-r}} = 15 \text{ m}^2/\text{kg}$, $l_{\text{v-r}} = 38 \text{ cm}^{-1}$, $\kappa_{\text{cnt}} = 3 \times 10^{-3} \text{ m}^2/\text{kg}$ and $a = 7$, which broadly match the H₂O fits

274 previously reported in Jeevanjee and Fueglistaler (2020). Table 1 summarizes the thermodynamic
 275 and spectral parameters used in this paper.

276 Figure 3 compares the idealized band models with line-by-line absorption cross-sections. Overall,
 277 the shape of the cross-sections is captured fairly well. The median CO₂ and H₂O cross-sections scale
 278 linearly with total pressure, as expected for pressure-broadening. The increasing H₂O absorption
 279 in response to warming around 1000 cm⁻¹ is also qualitatively captured by our grey continuum
 280 model, even though the H₂O continuum itself is actually not grey.

281 Figure 3 (right plots) shows that the slopes of the CO₂ and H₂O bands flatten as temperature
 282 increases, with roughly constant opacity in the band centers but increasing opacity in the band
 283 wings. This behavior is not captured by our simple models. Physically, absorption band slopes can
 284 depend on temperature due to the shifting population of different molecular excitation states. For
 285 example, the wings of the 667 cm⁻¹ CO₂ band consist of multiple smaller bands that correspond
 286 to transitions between excited states of CO₂ (so-called hot bands), while the center of the CO₂
 287 band is dominated by transitions to/from the ground state of CO₂. As temperature rises more CO₂
 288 molecules leave the ground state and access excited states, which in turn preferentially increases
 289 the opacity in the wings of the CO₂ band. To keep our parameterizations simple, however, we do
 290 not attempt to model the temperature-dependence of the band slopes.

291 3. Spectral Framework

292 *a. The emission-level approximation*

293 To decompose the net longwave feedback into its spectral components we first need to consider
 294 the outgoing longwave flux (OLR) of a vertical column. At a spectral wavenumber ν , the column's
 295 longwave flux varies vertically according to the monochromatic optical thickness τ^* and the angle
 296 $\cos(\theta)$ with which radiation propagates through the column. Assuming that the atmosphere's
 297 longwave radiation follows a known angular distribution, e.g., isotropic, these quantities can be
 298 combined into the vertical coordinate $\tau = \tau^*/\cos(\bar{\theta})$. Here $\cos(\bar{\theta})$ describes the average angle of
 299 propagation, and τ varies from $\tau = 0$ at the TOA to $\tau = \tau_{\text{surf}}$ at the surface (e.g. Pierrehumbert
 300 2010). The column's OLR is then equal to

$$\text{OLR} = \int_0^\infty \pi B_\nu(T_s) e^{-\tau_{\text{surf}}} d\nu + \int_0^\infty \int_0^{\tau_{\text{surf}}} \pi B_\nu(T(\tau)) e^{-\tau} d\tau d\nu. \quad (14)$$

TABLE 1. List of parameters and, where applicable, assumed values.

Parameter name	Explanation	Assumed value
Thermodynamic parameters		
T_0	Reference temperature for saturation vapor pressure power-law	300 K
γ_{wv}	Exponent in saturation vapor pressure power-law	18
γ_{lr}	Exponent in bulk lapse rate temperature-pressure power-law	Computed using Eqn. 9 (Section 5), or derived from data (Section 6)
Spectral parameters		
$\cos(\bar{\theta})$	Inverse angular diffusivity factor	3/5
p_0	Reference pressure for absorption cross-sections	1 bar
κ_0	Absorption cross-section in center of CO ₂ band	500 m ² /kg
ν_0	Wavenumber of the center of the CO ₂ band	667.5 cm ⁻¹
l_ν	Decay rate of the CO ₂ absorption cross-section in wavenumber space	10.2 cm ⁻¹
κ_{rot}	Absorption cross-section in center of H ₂ O rotation band	165 m ² /kg
ν_{rot}	Wavenumber of the center of the H ₂ O rotation band	150 cm ⁻¹
l_{rot}	Decay rate of the H ₂ O absorption cross-section in wavenumber space in the rotation band	55 cm ⁻¹
κ_{v-r}	Absorption cross-section in center of H ₂ O vibration-rotation band	15 m ² /kg
ν_{v-r}	Wavenumber of the center of the H ₂ O vibration-rotation band	1500 cm ⁻¹
l_{v-r}	Decay rate of the H ₂ O absorption cross-section in wavenumber space in the vibration-rotation band	38 cm ⁻¹
κ_{rot}	Grey absorption cross-section of H ₂ O continuum	3×10^{-3} m ² /kg
α	Exponent of H ₂ O continuum temperature-dependence	7
Analytic model parameters		
T_{strat}	Stratospheric temperature	200 K
c_{surf}	Scaling constant for surface feedback	0.8 (bulk lapse rate)/0.8 (moist adiabat)
c_{H_2O}	Scaling constant for H ₂ O band feedback	0.6 (bulk lapse rate)/1.0 (moist adiabat)
c_{cnt}	Scaling constant for H ₂ O continuum feedback	0.4 (bulk lapse rate)/0.4 (moist adiabat)
c_{CO_2}	Scaling constant for CO ₂ band feedback	0.7 (bulk lapse rate)/0.9 (moist adiabat)

301 The optical thicknesses τ and τ_{surf} are functions of ν , so the order of integration cannot be switched.
 302 Physically, the first term corresponds to the surface's emission to space, while the second term
 303 corresponds to an integral of the emission coming from each vertical level in the atmosphere.

304 The emission-level or radiating-level approximation states that the atmosphere's emission to
 305 space (the second integral in Equation 14) originates from the vertical level at which optical
 306 thickness τ is order unity. The intuition behind the emission-level approximation is that levels of
 307 the atmosphere for which $\tau \ll 1$ are optically thin and do not contribute much to the TOA flux,
 308 while most emission from levels with $\tau \gg 1$ is absorbed by the overlying atmosphere and so its
 309 contribution to the TOA flux is also small. The emission level has been defined at slightly different
 310 values of τ , but all definitions agree on a value of order unity (Pierrehumbert 2010; Jeevanjee
 311 et al. 2021b). For simplicity, we define the emission level here as the level at which $\tau = 1$. The
 312 temperature at this level is then the emission level temperature, $T_{rad} \equiv T(\tau = 1)$, so

$$OLR \approx \int_0^\infty \pi B_\nu(T_s) e^{-\tau_{surf}} d\nu + \int_0^\infty \pi B_\nu(T_{rad}(\nu)) d\nu. \quad (15)$$

313 Given the emission-level approximation, the clear-sky longwave feedback is determined by how
 314 the surface emission and the atmospheric emission change in response to warming,

$$\begin{aligned}
 -\lambda_{LW} &= \frac{d\text{OLR}}{dT_s} \\
 &\approx \int_0^\infty \pi \frac{dB_\nu}{dT} \Big|_{T_s} e^{-\tau_{\text{surf}}} d\nu + \int_0^\infty \pi \frac{dB_\nu}{dT} \Big|_{T_{\text{rad}}} \frac{dT_{\text{rad}}}{dT_s} d\nu.
 \end{aligned} \tag{16}$$

315 The minus sign ensures consistency with the sign convention used in most climate studies: OLR
 316 typically increases in response to surface warming, so $\lambda_{LW} < 0$. Note that Equation 16 does not
 317 contain any terms $\propto d\tau_{\text{surf}}/dT_s$ because the resulting contribution to change in the surface emission
 318 decreases with warming at exactly the same rate as the atmospheric emission increases (this can
 319 be seen by differentiating Eqn. 14 first before applying the emission-level approximation).

320 *b. Spectral feedback decomposition*

321 The net feedback in Equation 16 can be decomposed into multiple spectral regions or bands.
 322 The surface term dominates in the window region where $\tau_{\text{surf}} < 1$ and the feedback is primarily
 323 a function of surface temperature T_s . The atmospheric emission dominates where $\tau_{\text{surf}} > 1$, and
 324 its magnitude primarily depends on the derivative dT_{rad}/dT_s . As we show below, dT_{rad}/dT_s
 325 differs depending on the opacity source at a given wavenumber. In this work we only consider
 326 Earth's dominant greenhouse gases, CO₂ and H₂O, where H₂O's radiative effect additionally varies
 327 between the H₂O bands and the H₂O continuum, so we split the spectral integral into four terms:

$$\begin{aligned}
 -\lambda_{LW} &= \int_{\text{surf}} \pi \frac{dB_\nu}{dT} \Big|_{T_s} e^{-\tau_{\text{surf}}} d\nu + \int_{\text{CO}_2} \pi \frac{dB_\nu}{dT} \Big|_{T_{\text{CO}_2}} \frac{dT_{\text{CO}_2}}{dT_s} d\nu + \\
 &\quad \int_{\text{H}_2\text{O}} \pi \frac{dB_\nu}{dT} \Big|_{T_{\text{H}_2\text{O}}} \frac{dT_{\text{H}_2\text{O}}}{dT_s} d\nu + \int_{\text{cnt}} \pi \frac{dB_\nu}{dT} \Big|_{T_{\text{cnt}}} \frac{dT_{\text{cnt}}}{dT_s} d\nu \\
 &= -(\lambda_{\text{surf}} + \lambda_{\text{CO}_2} + \lambda_{\text{H}_2\text{O}} + \lambda_{\text{cnt}}),
 \end{aligned} \tag{17}$$

328 where T_{CO_2} , $T_{\text{H}_2\text{O}}$ and T_{cnt} are the emission temperatures in the CO₂ band, the H₂O band, and the
 329 H₂O continuum respectively (the wavenumber range of each integral is discussed in Section 5a).
 330 Based on the emitter, we refer to the four feedback terms as the surface feedback (λ_{surf}), the CO₂
 331 band feedback (λ_{CO_2}), the (non-Simpsonian) H₂O band feedback ($\lambda_{\text{H}_2\text{O}}$), and the H₂O continuum
 332 feedback (λ_{cnt}).

333 Our spectral decomposition complements the conventional feedback decomposition which splits
334 λ_{LW} into Planck, Lapse-Rate, and Water Vapor (or Relative Humidity) feedbacks. The surface
335 feedback λ_{surf} measures the OLR increase due to surface warming while keeping the atmosphere
336 fixed. This term is identical to the surface contribution of the Planck feedback, or “surface kernel”,
337 in the conventional decomposition (Soden et al. 2008). As for the atmospheric feedback, Equation
338 16 shows that it depends on the *total* derivative of T_{rad} , that is, on dT_{rad}/dT_s . The conventional
339 decomposition can be interpreted as splitting the total derivative dT_{rad}/dT_s up into various partial
340 derivatives (uniform warming versus lapse-rate versus water vapor changes), while using a single,
341 spectrally-averaged T_{rad} . In contrast, our decomposition splits the atmosphere’s feedback into
342 three different bands, but still retains the total derivative dT_{rad}/dT_s in each band. In principle
343 our decomposition could be split further to recover the conventional decomposition. That is, one
344 could further decompose dT_{rad}/dT_s in each band into partial derivatives of T_{rad} that correspond to
345 vertically-uniform warming, lapse-rate warming, and water-vapor changes – see Jeevanjee et al.
346 (2021a) for more details. Here, however, we do not pursue this approach because our analytic
347 expressions are general enough to predict T_{rad} and the total derivative dT_{rad}/dT_s .

348 We use relative humidity as the state variable throughout this paper, so the analytic results are
349 compatible with papers that argue for the use of relative humidity in feedback decompositions
350 instead of specific humidity (Held and Shell 2012; Jeevanjee et al. 2021a). In the fixed-RH
351 framework the conventional Water Vapor feedback is replaced by a Relative Humidity feedback,
352 which measures the clear-sky feedback due to RH changes. It is worth noting that the RH feedback
353 is small in individual climate models, and its multi-model mean is close to zero (Zelinka et al.
354 2020). In the derivations below we therefore treat RH as an external parameter whose value is
355 assumed constant under surface warming.

356 *c. Line-by-line calculations*

357 To calculate spectral feedbacks numerically we use a 1D line-by-line model, PyRADS (Koll and
358 Cronin 2018). The model’s radiative transfer includes HITRAN2016 CO₂ and H₂O absorption data
359 as well as the H₂O component of the MTCKD continuum version 3.2 (Mlawer et al. 2012; Gordon
360 et al. 2017). Calculations cover the spectral range 0.1-2500 cm⁻¹ with a resolution of $\Delta\nu = 0.01$
361 cm⁻¹, while the vertical resolution is 50 points in log-pressure. In general the angular distribution

362 of longwave radiation $\cos(\bar{\theta})$ varies in the vertical as well as across wavenumber (Li 2000; Feng
 363 and Huang 2019); however, a common approximation is to assume $\cos(\bar{\theta}) = 3/5$ (Elsasser 1942),
 364 which is also used here.

365 The 1D calculations assume the atmosphere’s temperature profile follows either a moist adiabat or
 366 a power law temperature-pressure profile that is consistent with our bulk lapse rate approximation.
 367 In both cases the troposphere is capped by a tropopause at 200 K, while the overlying stratosphere
 368 is isothermal at the same temperature. Relative humidity in the troposphere is vertically uniform
 369 while the H₂O mass fraction in the stratosphere is set equal to its value at the tropopause. CO₂ is
 370 treated as uniformly mixed in the vertical and fixed with respect to surface temperature. Because
 371 we are considering a wide range of surface temperatures, across which the tropopause pressure
 372 varies substantially, we vary the vertical grid-spacing in PyRADS: for each surface temperature,
 373 the model top pressure is set to a slightly lower value than the estimated tropopause pressure based
 374 on our bulk lapse rate formulation, which ensures the model’s top is always in the stratosphere and
 375 the tropopause is well resolved.

376 The spectrally-resolved feedback is the difference in the spectrally-resolved outgoing longwave
 377 flux, OLR_v , between a base state and a perturbed state with warmed surface and atmosphere,

$$-\lambda_v = \frac{\text{OLR}_v(T_s + \Delta T_s, \vec{T} + \Delta \vec{T}) - \text{OLR}_v(T_s, \vec{T})}{\Delta T_s}. \quad (18)$$

378 We use $\Delta T_s = 1$ K, while $\Delta \vec{T}$ denotes the atmospheric temperature perturbation caused by the
 379 surface warming ΔT_s . Because relative humidity is kept fixed, the atmospheric warming $\vec{T} + \Delta \vec{T}$
 380 also implies an increase in specific humidity.

381 Previous work has used various approaches to interpret line-by-line output. Seeley and Jeevanjee
 382 (2021) defined CO₂ versus H₂O bands based on the column-integrated, spectrally-smoothed optical
 383 thickness of CO₂ and H₂O. However, the behavior of H₂O differs strongly between the H₂O bands
 384 and the H₂O continuum, and it is difficult to distinguish these terms based on column-integrated
 385 optical thicknesses. For example, the H₂O continuum might have a larger integrated optical
 386 thickness at some wavenumber than the H₂O bands, but because continuum absorption decays
 387 more rapidly with altitude than band absorption ($\kappa_{\text{cnt}} \propto e^*(T)$ versus $\kappa_{\text{H}_2\text{O}} \propto p$) the emission at the
 388 level where $\tau \sim 1$ could still be determined by the H₂O bands.

389 Instead we first split the net feedback into its contributions from the surface versus atmosphere.
 390 The spectrally-resolved surface feedback is the feedback in response to surface-only warming while
 391 keeping the atmosphere fixed,

$$-\lambda_{\text{surf}}^{\nu} = \frac{\text{OLR}_{\nu}(T_s + \Delta T_s, \vec{T}) - \text{OLR}_{\nu}(T_s, \vec{T})}{\Delta T_s}. \quad (19)$$

392 If we integrate $\lambda_{\text{surf}}^{\nu}$ over all wavenumbers we get the surface feedback λ_{surf} , equivalent to the
 393 surface kernel of Soden et al. (2008). The atmospheric feedback is equal to the difference between
 394 λ_{ν} and $\lambda_{\text{surf}}^{\nu}$,

$$-\lambda_{\text{atm}}^{\nu} = \frac{\text{OLR}_{\nu}(T_s, \vec{T} + \Delta \vec{T}) - \text{OLR}_{\nu}(T_s, \vec{T})}{\Delta T_s}. \quad (20)$$

395 We split $\lambda_{\text{atm}}^{\nu}$ into different bands based on the spectrally-resolved emission pressures of CO₂,
 396 H₂O, and the H₂O continuum. For each absorber PyRADS computes the optical thickness as
 397 a function of pressure and wavenumber, $\tau(p, \nu)$. We define the CO₂ emission pressure as the
 398 pressure at which the optical thickness of CO₂ is equal to unity,

$$\tau_{\text{CO}_2}(p_{\text{rad}}, \nu) = 1, \quad (21)$$

399 which can be solved in each wavenumber bin to find $p_{\text{rad}}(\nu)$ (in practice we interpolate to find
 400 the pressure at which $\log[\tau] = 0$). The emission pressures of H₂O and the H₂O continuum are
 401 determined for each wavenumber bin in the same manner. The CO₂ band feedback λ_{CO_2} is then
 402 the integral of $\lambda_{\text{atm}}^{\nu}$ over all wavenumbers at which CO₂ has the smallest emission pressure, the
 403 H₂O band feedback $\lambda_{\text{H}_2\text{O}}$ is the integral of $\lambda_{\text{atm}}^{\nu}$ over all wavenumbers at which H₂O has the
 404 smallest emission pressure, and so on. The spectral decomposition is recomputed each time the
 405 atmosphere or surface state is varied, thereby allowing us to capture the state-dependence of the
 406 longwave feedback not just due to changes in the atmosphere's and surface's emission but also due
 407 to changes in the width of spectral bands. We note that this approach is justified if one emitter
 408 clearly dominates the atmosphere's emission at a given wavenumber, such that its emission pressure
 409 p_{rad} is much lower than that of any other emitters, but could be misleading if two emitters have
 410 very similar emission pressures. In practice, H₂O and CO₂ absorption cross-sections decrease

411 quasi-exponentially away from their band centers (see Section 2), which means the wavenumber
 412 range over which two absorbers can have a similar emission pressure is limited.

413 4. Emission temperatures

414 The feedbacks are set by the temperatures at the $\tau = 1$ levels, so we seek analytic expressions for
 415 the emission temperatures T_{CO_2} , $T_{\text{H}_2\text{O}}$ and T_{cnt} . The optical thickness of a generic absorber is

$$\tau = \int \kappa q \frac{dp}{g \cos(\bar{\theta})}, \quad (22)$$

416 where κ is the absorption cross-section and q is the absorber's mass-specific concentration. We
 417 use this equation to derive expressions for the emission temperatures by first writing the optical
 418 thickness in each band as a function of atmospheric temperature, then inverting these relations to
 419 find the emission temperature at the $\tau = 1$ level.

420 a. CO_2

421 CO_2 is well-mixed in the atmosphere so its mass-specific concentration q_{CO_2} is vertically uniform.
 422 As discussed in Section 2, its absorption cross-section depends linearly on pressure due to pressure
 423 broadening and can be written as $\kappa_{\text{CO}_2}(\nu, p) = \kappa_{\text{CO}_2}^*(\nu)(p/p_0)$, where $\kappa_{\text{CO}_2}^*$ captures the wavenumber-
 424 dependence of the CO_2 absorption cross-section, $\kappa_{\text{CO}_2}^* \propto \exp(-|\nu - \nu_0|/l_\nu)$, while p_0 is an reference
 425 pressure. Because we previously chose p_0 to be equal to the dry surface pressure, one can write
 426 $\kappa_{\text{CO}_2}^*(\nu) \approx \kappa_{\text{CO}_2}^*(\nu, p_s)$ (the approximation is due to neglecting the mass contribution of water vapor
 427 to p_s). The optical thickness at a vertical level with temperature and pressure (T, p) is then

$$\begin{aligned} \tau_{\text{CO}_2} &= \int_0^p \kappa_{\text{CO}_2}^* \left(\frac{p'}{p_s} \right) q_{\text{CO}_2} \frac{dp'}{g \cos(\bar{\theta})}, \\ &= \frac{\kappa_{\text{CO}_2}^*}{2g \cos(\bar{\theta}) p_s} q_{\text{CO}_2} p^2, \\ &= \frac{\kappa_{\text{CO}_2}^* p_s}{2g \cos(\bar{\theta})} q_{\text{CO}_2} \left(\frac{p}{p_s} \right)^2 \\ &= \frac{\kappa_{\text{CO}_2}^* p_s}{2g \cos(\bar{\theta})} q_{\text{CO}_2} \left(\frac{T}{T_s} \right)^{2/\gamma_{\text{r}}} \\ &\equiv \tau_{\text{CO}_2}^*(\nu) q_{\text{CO}_2} \times \left(\frac{T}{T_s} \right)^{2/\gamma_{\text{r}}}, \end{aligned} \quad (23)$$

428 where the fourth step uses the bulk lapse rate. Note that all spectroscopic parameters as well as
 429 p_s and g are combined into a reference optical thickness, $\tau_{\text{CO}_2}^*(\nu)$, which encapsulates how CO_2
 430 absorption varies with respect to wavenumber ν , surface pressure p_s , and gravity g , but which can
 431 be treated as constant in response to warming.

432 *b. Non-Simpsonian H_2O*

433 As for CO_2 , the absorption cross-section of H_2O scales linearly with pressure and can be written
 434 as $\kappa_{\text{H}_2\text{O}}(\nu, p) = \kappa_{\text{H}_2\text{O}}^*(\nu)(p/p_s)$. We use the Clausius-Clapeyron power law approximation to write
 435 the saturation specific humidity as $q^* \approx R_d/R_v \times e_0^*/p \times (T/T_0)^{\gamma_{\text{wv}}}$ and the specific humidity as
 436 $q = \text{RH} \times q^*$. The optical thickness of H_2O at a level (T, p) is then

$$\begin{aligned}
 \tau_{\text{H}_2\text{O}} &= \int_0^p \kappa_{\text{H}_2\text{O}}^* \left(\frac{p'}{p_s} \right) q \frac{dp'}{g \cos(\bar{\theta})}, \\
 &\approx \text{RH} \frac{\kappa_{\text{H}_2\text{O}}^* e_0^* R_d}{g \cos(\bar{\theta}) R_v} \times \int_0^p \left(\frac{p'}{p_s} \right) \left(\frac{T'}{T_0} \right)^{\gamma_{\text{wv}}} \frac{dp'}{p'} \\
 &= \text{RH} \frac{\kappa_{\text{H}_2\text{O}}^* e_0^* R_d}{g \cos(\bar{\theta}) R_v} \times \int_0^T \left(\frac{T'}{T_s} \right)^{1/\gamma_{\text{lr}}} \left(\frac{T'}{T_0} \right)^{\gamma_{\text{wv}}} \frac{1}{\gamma_{\text{lr}}} \frac{dT'}{T'} \\
 &= \text{RH} \frac{\kappa_{\text{H}_2\text{O}}^* e_0^* R_d}{g \cos(\bar{\theta}) R_v} \frac{1}{\gamma_{\text{lr}}} \left(\frac{T_0}{T_s} \right)^{1/\gamma_{\text{lr}}} \times \int_0^T \left(\frac{T'}{T_0} \right)^{\gamma_{\text{wv}} + \frac{1}{\gamma_{\text{lr}}}} \frac{dT'}{T'} \\
 &= \text{RH} \frac{\kappa_{\text{H}_2\text{O}}^* e_0^* R_d}{g \cos(\bar{\theta}) R_v} \frac{1}{1 + \gamma_{\text{wv}} \gamma_{\text{lr}}} \times \left(\frac{T}{T_0} \right)^{\frac{1 + \gamma_{\text{wv}} \gamma_{\text{lr}}}{\gamma_{\text{lr}}}} \left(\frac{T_0}{T_s} \right)^{1/\gamma_{\text{lr}}} \\
 &\equiv \text{RH} \tau_{\text{H}_2\text{O}}^*(\nu) \frac{1}{1 + \gamma_{\text{wv}} \gamma_{\text{lr}}} \times \left(\frac{T}{T_0} \right)^{\frac{1 + \gamma_{\text{wv}} \gamma_{\text{lr}}}{\gamma_{\text{lr}}}} \left(\frac{T_0}{T_s} \right)^{1/\gamma_{\text{lr}}}. \tag{24}
 \end{aligned}$$

437 where the second step uses the Clausius-Clapeyron power law and also replaces the water vapor
 438 concentration in the stratosphere with the water vapor concentration of a moist adiabat that extends
 439 all the way to the top-of-atmosphere. We again define a reference optical thickness, $\tau_{\text{H}_2\text{O}}^*(\nu)$, which
 440 encapsulates how H_2O band absorption varies with respect to wavenumber ν , and gravity g , but
 441 which is independent of temperature.

442 *c. H_2O Continuum*

443 Absorption by the H_2O continuum strengthens in response to increasing water vapor concen-
 444 trations and weakens in response to warming, $\kappa_{\text{H}_2\text{O}, \text{cnt}} = \kappa_{\text{cnt}} \times \text{RH} e^*(T)/e^*(T_0) \times (T/T_0)^{-a}$. The

445 optical thickness of the continuum is then

$$\begin{aligned}
\tau_{\text{cnt}} &= \text{RH} \int_0^p \kappa_{\text{cnt}} \frac{e^*(T')}{e^*(T_0)} \left(\frac{T'}{T_0}\right)^{-a} q \frac{dp'}{g \cos(\bar{\theta})}, \\
&\approx \text{RH}^2 \frac{\kappa_{\text{cnt}} e_0^*}{g \cos(\bar{\theta})} \frac{R_d}{R_v} \times \int_0^T \left(\frac{T'}{T_0}\right)^{2\gamma_{\text{wv}}-a} \frac{dT'}{p}, \\
&= \text{RH}^2 \frac{\kappa_{\text{cnt}} e_0^*}{g \cos(\bar{\theta})} \frac{R_d}{R_v} \times \int_0^T \left(\frac{T'}{T_0}\right)^{2\gamma_{\text{wv}}-a} \frac{1}{\gamma_{\text{lr}}} \frac{dT'}{T'}, \\
&= \text{RH}^2 \frac{\kappa_{\text{cnt}} e_0^*}{g \cos(\bar{\theta})} \frac{R_d}{R_v} \frac{1}{(2\gamma_{\text{wv}}-a)\gamma_{\text{lr}}} \times \left(\frac{T}{T_0}\right)^{2\gamma_{\text{wv}}-a}, \\
&\equiv \text{RH}^2 \tau_{\text{cnt}}^* \frac{1}{(2\gamma_{\text{wv}}-a)\gamma_{\text{lr}}} \times \left(\frac{T}{T_0}\right)^{2\gamma_{\text{wv}}-a}, \tag{25}
\end{aligned}$$

446 where the second and third steps make the same assumptions as the derivation for the H₂O band.
447 Here the reference optical thickness, τ_{cnt}^* encapsulates how the H₂O self-continuum varies with
448 respect to gravity g but has no dependence on wavenumber or temperature.

449 *d. Emission temperatures*

450 By setting $\tau = 1$ and inverting the above relations, we arrive at the emission temperatures in the
451 CO₂ band, the H₂O band and the H₂O self-continuum:

$$T_{\text{CO}_2} = T_s \left(\frac{1}{\tau_{\text{CO}_2}^*(\nu) q_{\text{CO}_2}} \right)^{\gamma_{\text{lr}}/2} \tag{26a}$$

$$T_{\text{H}_2\text{O}} = T_0 \left(\frac{1 + \gamma_{\text{wv}} \gamma_{\text{lr}}}{\tau_{\text{H}_2\text{O}}^*(\nu) \text{RH}} \right)^{\frac{\gamma_{\text{lr}}}{1 + \gamma_{\text{wv}} \gamma_{\text{lr}}}} \left(\frac{T_s}{T_0} \right)^{\frac{1}{1 + \gamma_{\text{wv}} \gamma_{\text{lr}}}} \tag{26b}$$

$$T_{\text{cnt}} = T_0 \left(\frac{(2\gamma_{\text{wv}} - a) \gamma_{\text{lr}}}{\tau_{\text{cnt}}^* \text{RH}^2} \right)^{\frac{1}{2\gamma_{\text{wv}} - a}}. \tag{26c}$$

452 To interpret these emission temperatures, consider whether a given emitter stabilizes or destabi-
453 lizes Earth's climate. For CO₂ it is easy to see that the feedback is always stabilizing. Ignoring
454 lapse rate changes we have $T_{\text{CO}_2} \propto T_s$, so $dT_{\text{CO}_2}/dT_s > 0$. More intuitively, the optical thickness of

455 CO₂ can be written as

$$\tau_{\text{CO}_2} \propto \left(\frac{T}{T_s}\right)^{2/\gamma_{\text{lr}}} = \left(\frac{p}{p_s}\right)^2. \quad (27)$$

456 The emission level of CO₂ is therefore a fixed function of pressure at a given atmospheric CO₂
 457 concentration. Given that the atmosphere's temperature at a fixed pressure level always increases
 458 in response to surface warming, T_{CO_2} also has to increase under warming. This effect can be thought
 459 of as a spectral radiator fin, and is also valid if the lapse rate γ_{lr} varies under surface warming. It
 460 implies that even if the atmosphere stops emitting more at all other wavenumbers, so $dT_{\text{rad}}/dT_s = 0$
 461 outside the CO₂ band, the presence of CO₂ still allows the atmosphere to shed more energy to
 462 space in response to surface warming (Seeley and Jeevanjee 2021).

463 Next, our expressions suggest that the feedback from H₂O is small and, to first order, might
 464 be negligible. Equation 26b shows $T_{\text{H}_2\text{O}} \propto T_s^{1/(1+\gamma_{\text{wv}}\gamma_{\text{lr}})}$, where representative values for Earth's
 465 tropics are $\gamma_{\text{wv}} \sim 20$ and $\gamma_{\text{lr}} \sim 1/7$, so the H₂O emission temperature only depends weakly on
 466 surface temperature, $T_{\text{H}_2\text{O}} \propto T_s^{1/4}$. This small exponent is closely related to Simpson's "paradox"
 467 (Ingram 2010) or Simpson's "law" (Jeevanjee et al. 2021a), which state that $T_{\text{H}_2\text{O}}$ is approximately
 468 independent of surface temperature. In the limit $\gamma_{\text{wv}}\gamma_{\text{lr}} = d \ln e^* / d \ln p \gg 1$, that is, if water vapor
 469 increases much faster in the vertical than the total atmospheric mass, then

$$T_{\text{H}_2\text{O}} \approx T_0 \left(\frac{\gamma_{\text{wv}}\gamma_{\text{lr}}}{\tau_{\text{H}_2\text{O}}^*(\nu)RH} \right)^{\frac{1}{\gamma_{\text{wv}}}}, \quad (28)$$

470 and $T_{\text{H}_2\text{O}}$ ceases to depend on T_s . If the lapse rate is also independent of T_s we recover Simpson's
 471 law:

$$\frac{dT_{\text{H}_2\text{O}}}{dT_s} \approx 0. \quad (29)$$

472 In reality, however, water vapor dominates much of the spectrum so even minor deviations from
 473 Simpson's law can have a notable impact on the longwave feedback. Deviations arise because the
 474 H₂O optical thickness is sensitive to pressure broadening and because changes in γ_{lr} modify the
 475 total water vapor path inside the atmospheric column. For present-day Earth the net impact of these

476 changes is to increase the H₂O emission temperature under surface warming: since $T_{\text{H}_2\text{O}} \propto T_s^{1/4}$, it
 477 follows that $dT_{\text{H}_2\text{O}}/dT_s > 0$, which means the H₂O bands tend to stabilize Earth's climate.

478 Finally, T_{cnt} has no direct dependence on surface temperature, but is sensitive to lapse rate
 479 changes. If we take the continuum's emission temperature (Eqn. 26c), and assume that the direct
 480 temperature-dependence of the continuum $a \sim 7$ is much smaller than its temperature-dependence
 481 due to the Clausius-Clapeyron relation, $2\gamma_{\text{wv}} \sim 40$, we have

$$T_{\text{cnt}} \propto T_0 \times [\gamma_{\text{lr}}]^{1/(2\gamma_{\text{wv}})}. \quad (30)$$

482 Because the lapse rate γ_{lr} decreases under surface warming we have $dT_{\text{cnt}}/dT_s = dT_{\text{cnt}}/d\gamma_{\text{lr}} \times$
 483 $d\gamma_{\text{lr}}/dT_s < 0$. Physically, this effect can be understood by considering the impact of γ_{lr} on the
 484 atmosphere's total water vapor path. If one decreases the lapse rate γ_{lr} while keeping T_s fixed,
 485 the atmospheric column warms and thus can store more water vapor. To still maintain an optical
 486 thickness of unity then requires that the continuum's emission level moves to colder temperatures.
 487 Our expressions thus predict that the H₂O continuum gives rise to a destabilizing feedback.

488 *e. Comparison against LBL calculations*

489 Equations 26a - 26c predict how Earth's emission temperature varies in response to changes in
 490 T_s , q_{CO_2} , γ_{lr} and RH. To test these equations we perform four sets of numerical experiments with
 491 PyRADS in which we variously change T_s , q_{CO_2} , γ_{lr} , and RH while holding the other parameters
 492 fixed. The default values are $T_s = 290$ K, 400 ppm of CO₂, $\gamma_{\text{lr}} = 2/7$, and RH = 0.8. To match
 493 our underlying assumptions we assume a bulk tropospheric lapse rate, so $T = T_s(p/p_s)^{\gamma_{\text{lr}}}$, which
 494 means the temperature profile differs from an adiabat if $\gamma_{\text{lr}} < 2/7$. The troposphere is capped by
 495 an isothermal stratosphere which is kept fixed at $T_{\text{strat}} = 200$ K. Note that in Equations 26a - 26c
 496 the dependence on wavenumber only enters through the reference optical thicknesses $\tau_{\text{CO}_2}^*$, $\tau_{\text{H}_2\text{O}}^*$,
 497 and τ_{cnt}^* , which are evaluated using the cross-sections from Section 2. Because the cross-sections
 498 were fit independently, the analytic T_{rad} expressions do not contain any free tuning parameters.

499 To compare the analytic results against line-by-line calculations we first numerically compute the
 500 top-of-atmosphere spectral flux OLR_ν for a given set of $(T_s, q_{\text{CO}_2}, \gamma_{\text{lr}}, \text{RH})$. We then smooth OLR_ν
 501 with a median filter of width 50 cm^{-1} , before inverting it using the Planck function to find the

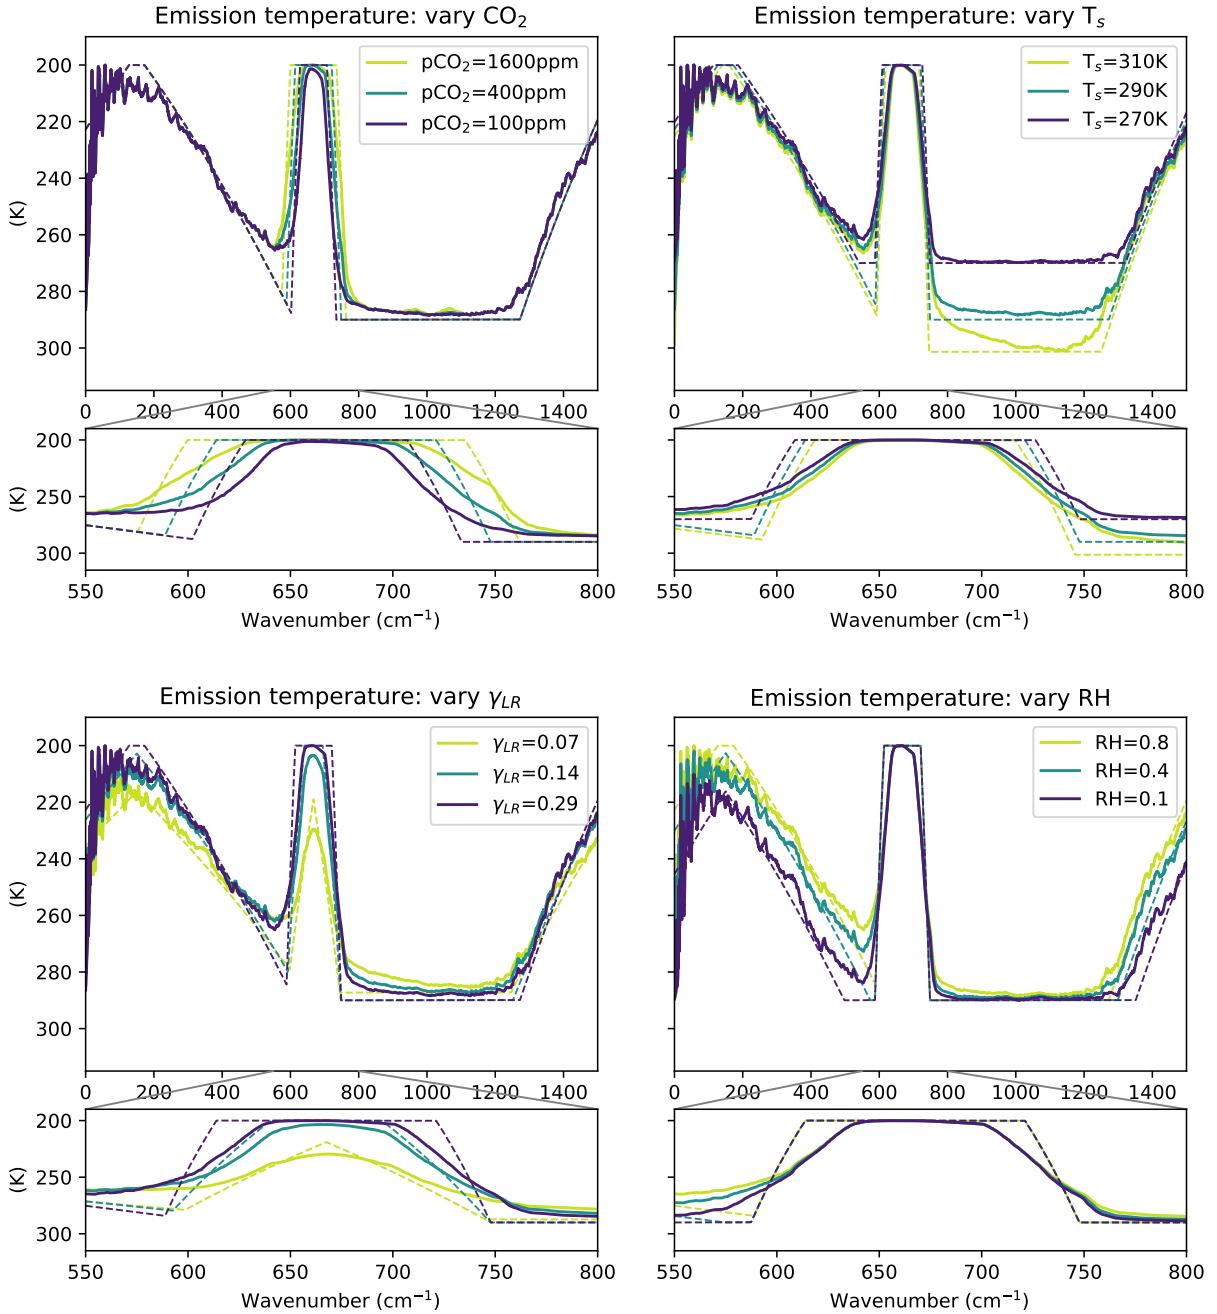

502 atmosphere’s emission temperature (also known as brightness temperature) at a given wavenumber.
 503 Finally, we combine our analytic expressions into a single emission temperature via

$$T_{\text{rad}} = \max [T_{\text{strat}}, \min [T_s, T_{\text{CO}_2}, T_{\text{H}_2\text{O}}, T_{\text{cnt}}]], \quad (31)$$

504 to compare directly with temperatures from line-by-line calculations.

505 Figure 4 demonstrates that the analytic results compare favorably against numerical calculations.
 510 Even though the analytic T_{rad} shapes are idealized compared to the numerical calculations, the
 511 overall response of T_{rad} to perturbations is captured well. First, increasing CO_2 concentration
 512 lowers T_{rad} around 667 cm^{-1} , which corresponds to the wings of the CO_2 band. This is simply a
 513 spectrally resolved view of how increasing CO_2 acts as a radiative forcing (Jeevanjee et al. 2021b).
 514 Second, warming the surface while keeping all other parameters fixed has multiple effects. The
 515 main impact is to increase the emission temperature in the window region between ~ 800 and 1200
 516 cm^{-1} . In addition there are secondary impacts: surface warming also shrinks the width of the CO_2
 517 band and slightly increases the emission temperature in the H_2O bands below 600 cm^{-1} and above
 518 1300 cm^{-1} (this latter effect is hard to see in Figure 4). The increased emission in the H_2O bands
 519 shows that Simpson’s law in Equation 29 is not exact, an effect that is captured by our analytic
 520 expressions. Third, reducing the lapse rate γ_{lr} preserves the width of the CO_2 band, but it flattens
 521 the steepness of its slopes and increases the emission temperature in the center of the band. In the
 522 H_2O bands, a smaller γ_{lr} while keeping T_s fixed also leads to a non-Simpsonian increase of the
 523 emission temperature in the H_2O bands. In contrast to the H_2O bands, the emission temperature
 524 of the H_2O continuum around 1000 cm^{-1} decreases as γ_{lr} is reduced. As discussed above, this is
 525 because the atmospheric water path increases with a smaller γ_{lr} , which reduces T_{cnt} . The feedback
 526 of the H_2O continuum therefore has the opposite sign as the H_2O bands, in line with the analytic
 527 results. Finally, reducing the relative humidity increases T_{rad} in all regions dominated by water
 528 vapor, both in the H_2O bands below 600 cm^{-1} /above 1300 cm^{-1} and in the H_2O continuum around
 529 1000 cm^{-1} , while the CO_2 band is unaffected.

530 Overall, Figure 4 underlines that comparatively simple physics is sufficient to explain the
 531 spectrally-resolved response of T_{rad} to different climate perturbations. To connect Figure 4 back
 532 to the total clear-sky longwave feedback we only need to consider how these changes in T_{rad} play

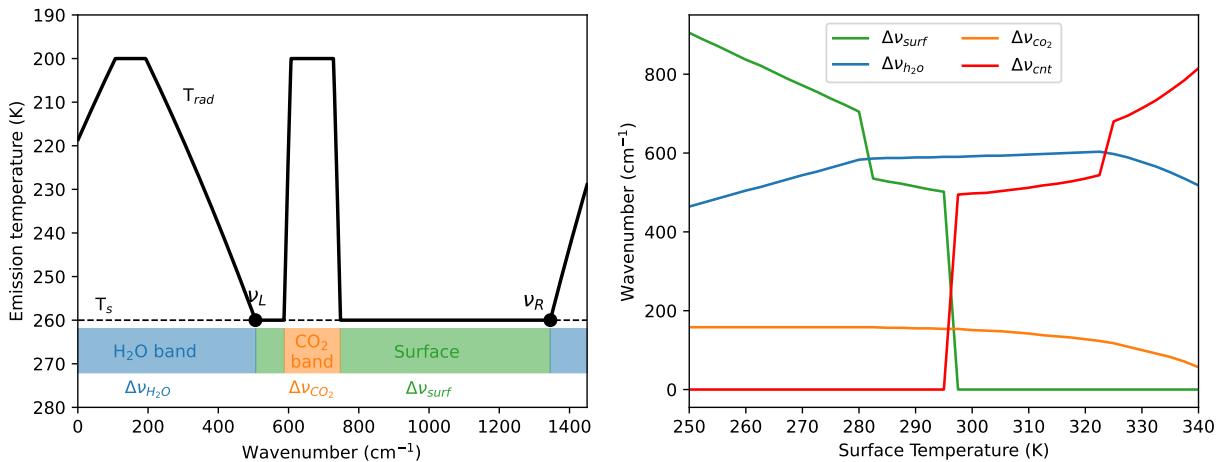

505 FIG. 4. Analytic emission temperatures (dashed), compared against numerical line-by-line results smoothed
 506 with a median filter of width 50 cm⁻¹. Large rows show the entire infrared spectrum, small rows are zoomed
 507 in on the CO₂ band. The y-axes are flipped so that emission temperature decreases going up, the same way
 508 temperature decreases with altitude in Earth's atmosphere.

533 out once we average them into spectral bands, and how multiple bands add up to determine the net
 534 longwave feedback.

535 5. Analytic Feedbacks

536 Having derived expressions for the emission temperature in different parts of the LW spectrum,
 537 and verified these expressions against line-by-line calculations, we can now derive analytic expres-
 538 sions for the four spectral feedbacks: λ_{surf} , λ_{CO_2} , $\lambda_{\text{H}_2\text{O}}$ and λ_{cnt} . Above each spectral feedback was
 539 defined as an integral over a wavenumber range (Eqn. 17), but the wavenumber ranges were not
 540 further specified. We therefore first define and estimate the width of the different spectral bands.

541 a. Band widths

542 FIG. 5. Illustration of spectral band widths. The emission temperature is equal to the emission temperature of
 543 whichever emitter is coldest, $T_{\text{rad}} = \min[T_{\text{CO}_2}, T_{\text{H}_2\text{O}}, T_{\text{cnt}}, T_s]$, or the stratospheric temperature. Left: Lines show
 544 the analytic T_{rad} (solid) and surface temperature T_s (dashed), while colored regions illustrate which emitters
 545 dominate in which band. The calculation shown uses $T_s=260$ K, RH = 0.8, and 400ppm of CO₂. Right:
 546 Band widths as a function of surface temperature, numerically calculated based on our emission temperature
 547 expressions. Here $\Delta\nu_{\text{H}_2\text{O}}$ refers only to the rotational band at wavenumbers lower than 1000 cm⁻¹. The jumps at
 548 ~280 K, ~295 K and ~325 K occur when the H₂O band starts intersecting the CO₂ band; when the continuum
 549 becomes opaque; and when the continuum becomes opaque on the left side of the CO₂ band, at wavenumbers
 550 less than about 600 cm⁻¹, respectively.

551 We define an absorption band as the spectral range in which a given absorber has the coldest
 552 emission temperature compared to all other absorbers (this is equivalent to the highest-altitude
 553 emission level), and thus dominates the column's emission to space. For example, the CO₂ band
 554 is defined as all wavenumbers in which $T_{\text{CO}_2} < \min[T_{\text{H}_2\text{O}}, T_{\text{cnt}}, T_s]$, as illustrated in Figure 5a. The
 555 width of the CO₂ band can then be computed from the two wavenumbers ν^{edge} which define the
 556 edges of the CO₂ band, which is where the emission temperature of CO₂ is equal to the emission
 557 temperatures of its neighboring absorbers: $T_{\text{CO}_2}(\nu^{edge}) = \min[T_{\text{H}_2\text{O}}(\nu^{edge}), T_{\text{cnt}}, T_s]$.

558 1) CO₂ BAND WIDTH

559 To estimate the width of the CO₂ band we consider three situations: (1) the CO₂ concentration
 560 q_{CO_2} is so low that even in the center of the CO₂ band the optical thickness is less than one; (2) a dry
 561 atmosphere in which there is no overlap between CO₂ and H₂O bands; and (3) a moist atmosphere
 562 in which there is some overlap between CO₂ and H₂O.

563 First, at very low CO₂ concentrations the band width of CO₂ is simply equal to zero. From the
 564 optical thickness of CO₂ (Eqn. 23), the column-integrated optical thickness in the middle of the
 565 CO₂ band is equal to $\tau_{\text{CO}_2}(\nu_0, T_s) = q_{\text{CO}_2} \tau_{\text{CO}_2}^*(\nu_0)$ so this occurs when

$$\Delta\nu_{\text{CO}_2} = 0, \quad \text{if } q_{\text{CO}_2} \tau_{\text{CO}_2}^*(\nu_0) < 1. \quad (32)$$

566 As a representative value, we evaluate $\tau_{\text{CO}_2}^*(\nu_0)$ using $\kappa_0 = 500 \text{ m}^2 \text{ kg}^{-1}$ from Section 2c. We find
 567 that the middle of the CO₂ band becomes optically thick above a CO₂ concentration of ~ 0.2 ppm.
 568 Note this value is only approximate, as our idealized band model deviates from real CO₂ absorption
 569 cross-section in the middle of the CO₂ band (see Fig. 3).

570 Second, at non-negligible CO₂ concentrations and low water vapor concentrations, CO₂-H₂O
 571 overlap is negligible. Physically, this occurs either when the surface temperature is cold or the
 572 relative humidity is low; for simplicity we refer to this as the "cold" regime. In this regime the
 573 edge of the CO₂ band can be defined as the wavenumber ν^{cold} at which T_{CO_2} intersects with the
 574 surface temperature T_s , $T_{\text{CO}_2}(\nu^{cold}) = T_s$. The emission temperature of CO₂ is equal to $T_{\text{CO}_2} = T_s \times$
 575 $(\tau_{\text{CO}_2}^* q_{\text{CO}_2})^{-\gamma_{\text{lr}}/2}$ (Eqn. 26a), while our model of CO₂ spectroscopy states $\tau_{\text{CO}_2}(\nu)^* \propto \exp(-|\nu - \nu_0|/l_\nu)$

576 (Eqn. 11). Combining the two equations yields

$$\nu^{cold} = \nu_0 \pm l_\nu \log(q_{\text{CO}_2} \tau_{\text{CO}_2}^*(\nu_0)), \quad (33)$$

577 where $\tau_{\text{CO}_2}^*(\nu_0) = \kappa_0(\nu_0)p_s/(2g)$ is the reference optical thickness in the center of the CO₂ band.

578 The overall width of the CO₂ band in the cold regime is therefore

$$\Delta\nu_{\text{CO}_2}^{cold} = 2l_\nu \log(q_{\text{CO}_2} \tau_{\text{CO}_2}^*(\nu_0)). \quad (34)$$

579 To estimate the order of magnitude of $\Delta\nu_{\text{CO}_2}^{cold}$ we again use $\kappa_0 = 500 \text{ m}^2 \text{ kg}^{-1}$ and a q_{CO_2} that
 580 corresponds to 400ppm of CO₂. The optical thickness in the center of the CO₂ band is $\tau_{\text{CO}_2}^*(\nu_0) \sim$
 581 2600. This large optical thickness decreases exponentially with wavenumber away from ν_0 , so that
 582 $T_{\text{CO}_2} = T_s$ only $\sim 80 \text{ cm}^{-1}$ away from ν_0 . Because CO₂'s band shape is symmetric about ν_0 , the
 583 present-day CO₂ band width is thus roughly 160 cm^{-1} .

584 Third, at high water vapor concentrations, surface emission is replaced by H₂O emission. Phys-
 585 ically, this occurs either when the surface temperature is hot and/or relative humidity is high; for
 586 simplicity we refer to this as the "hot" regime. In this regime we solve the CO₂ band width as
 587 $T_{\text{CO}_2}(\nu^{hot}) = T_{\text{H}_2\text{O}}(\nu^{hot})$. Because the CO₂ band decays much faster with wavenumber away from
 588 its band center than the H₂O band does ($l_\nu \sim 10 \text{ cm}^{-1}$ versus $l_{\text{rot}} \sim 55 \text{ cm}^{-1}$; see Table 1) we further
 589 approximate $T_{\text{H}_2\text{O}}$ as constant across the CO₂ band and equal to its value in the CO₂ band center
 590 $T_{\text{H}_2\text{O}}(\nu) \approx T_{\text{H}_2\text{O}}(\nu_0)$. Combining the emission temperature of CO₂ (Eqn. 26a) with our model of
 591 CO₂ spectroscopy (Eqn. 11),

$$\nu^{hot} = \nu_0 \pm l_\nu \log \left[q_{\text{CO}_2} \tau_{\text{CO}_2}^*(\nu_0) \left(\frac{T_{\text{H}_2\text{O}}(\nu_0)}{T_s} \right)^{\frac{2}{\gamma_r}} \right], \quad (35)$$

592 where the emission temperature of H₂O can be evaluated using Eqn. 26b. Physically speaking,
 593 the H₂O emission temperature is colder than the surface, $T_{\text{H}_2\text{O}}(\nu_0)/T_s < 1$, so our model correctly
 594 captures the fact that H₂O-CO₂ overlap decreases the width of the CO₂ band. Taking into account

595 all three regimes, the overall width of the CO₂ band is therefore

$$\Delta\nu_{\text{CO}_2} = \begin{cases} 0, & \text{if } q_{\text{CO}_2}\tau_{\text{CO}_2}^*(\nu_0) < 1 \\ 2 \times \min(\nu^{\text{hot}} - \nu_0, \nu^{\text{cold}} - \nu_0), & \text{if } q_{\text{CO}_2}\tau_{\text{CO}_2}^*(\nu_0) \geq 1. \end{cases} \quad (36)$$

596 2) H₂O BAND WIDTH

597 To determine the width of the H₂O band the potential overlap with CO₂ matters less because the
 598 CO₂ band is too narrow to block a significant portion of the emission by H₂O (at present-day CO₂
 599 concentrations). However, at high water vapor concentrations, competition between the H₂O bands
 600 and the H₂O continuum becomes important, so we again consider a “cold” and a “hot” regime. At
 601 low water vapor concentrations (physically, at cold temperature or low relative humidity) continuum
 602 absorption is negligible and we solve $T_{\text{H}_2\text{O}}(\nu^{\text{cold}}) = T_s$. Combining the emission temperature of
 603 H₂O (Eqn. 26b) with our H₂O band model (Eqn. 12), this leads to

$$\nu_L^{\text{cold}} = \nu_{\text{rot}} + l_{\text{rot}} \log \left(\frac{\text{RH}\tau_{\text{rot}}^*(\nu_{\text{rot}})}{1 + \gamma_{\text{wv}}\gamma_{\text{lr}}} \left(\frac{T_s}{T_0} \right)^{\gamma_{\text{wv}}} \right), \quad (37a)$$

$$\nu_R^{\text{cold}} = \nu_{\text{v-r}} - l_{\text{v-r}} \log \left(\frac{\text{RH}\tau_{\text{v-r}}^*(\nu_{\text{v-r}})}{1 + \gamma_{\text{wv}}\gamma_{\text{lr}}} \left(\frac{T_s}{T_0} \right)^{\gamma_{\text{wv}}} \right), \quad (37b)$$

604 where ν_L is the left edge of the window below $\sim 1000 \text{ cm}^{-1}$, and ν_R is the right edge of the
 605 window above $\sim 1000 \text{ cm}^{-1}$ (see Figure 5). The two H₂O bands have different spectral slopes, and
 606 subscript “rot” denotes quantities that are related to the rotational H₂O band at wavenumbers below
 607 1000 cm^{-1} while subscript “v-r” denotes quantities related to the vibrational-rotational H₂O band at
 608 wavenumbers above 1000 cm^{-1} (see Section 2). At high water vapor concentrations, the continuum
 609 cuts off emission from the surface so the H₂O band edge ν^{hot} is determined by $T_{\text{H}_2\text{O}}(\nu^{\text{hot}}) = T_{\text{cnt}}$.
 610 Using the emission temperature of H₂O (Eqn. 26b) and our H₂O band model, we find

$$\nu_L^{\text{hot}} = \nu_{\text{rot}} + l_{\text{rot}} \log \left[\frac{\text{RH}\tau_{\text{rot}}^*(\nu_{\text{rot}})}{1 + \gamma_{\text{wv}}\gamma_{\text{lr}}} \left(\frac{T_0}{T_s} \right)^{1/\gamma_{\text{lr}}} \left(\frac{T_{\text{cnt}}}{T_0} \right)^{\frac{1+\gamma_{\text{wv}}\gamma_{\text{lr}}}{\gamma_{\text{lr}}}} \right], \quad (38a)$$

$$\nu_R^{\text{hot}} = \nu_{\text{v-r}} - l_{\text{v-r}} \log \left[\frac{\text{RH}\tau_{\text{v-r}}^*(\nu_{\text{v-r}})}{1 + \gamma_{\text{wv}}\gamma_{\text{lr}}} \left(\frac{T_0}{T_s} \right)^{1/\gamma_{\text{lr}}} \left(\frac{T_{\text{cnt}}}{T_0} \right)^{\frac{1+\gamma_{\text{wv}}\gamma_{\text{lr}}}{\gamma_{\text{lr}}}} \right], \quad (38b)$$

611 where the continuum emission temperature is given by Eqn. 26c. Combining both regimes, the
 612 window width due to H₂O absorption is therefore

$$\begin{aligned}\Delta\nu_{\text{surf}}(T_s, \text{RH}, \gamma_{\text{lr}}) &= \nu_R - \nu_L \\ &= \max(\nu_R^{\text{cold}}, \nu_R^{\text{hot}}) - \min(\nu_L^{\text{cold}}, \nu_L^{\text{hot}}).\end{aligned}\quad (39)$$

613 Similar to the CO₂ band width, Equations 37 and 38 become invalid at very low RH or T_s because in
 614 those situations H₂O ceases to be optically thick at all wavenumbers (mathematically, this happens
 615 when RH or T_s become small enough that the logarithms in Eqns. 37 and 38 change sign). We do
 616 not consider the limit $\text{RH} \rightarrow 0$ in this paper, but care should be taken when applying our results to
 617 extremely dry or cold atmospheres.

618 Finally, our feedback expression for the H₂O band feedback requires us to separately specify the
 619 width of the rotational H₂O band below 1000 cm⁻¹. This width can be estimated by assuming
 620 that the rotational band always extends from 0 cm⁻¹ to the left edge of the window region ν_L
 621 (see Figure 5). Doing so presumes that H₂O is always optically thick at low wavenumbers around
 622 $\nu = 0$ cm⁻¹. While this assumption again breaks down in very cold or dry climates (the maximum
 623 absorption in the rotational band occurs around $\nu \sim 150$ cm⁻¹, not 0 cm⁻¹, so low wavenumbers
 624 could become optically thin even if the band center is still optically thick), in those climates the
 625 H₂O band feedback becomes negligible relative to the surface anyway. The width of the rotational
 626 H₂O band is then

$$\Delta\nu_{\text{H}_2\text{O}}(T_s, \text{RH}, \gamma_{\text{lr}}) \approx \nu_L - 0 = \min(\nu_L^{\text{cold}}, \nu_L^{\text{hot}}), \quad (40)$$

627 where the wavenumber ν_L denotes the left edge of the surface window (see above), as well as the
 628 right edge of the rotational H₂O band.

629 *b. Surface Feedback*

630 The surface feedback is given by

$$-\lambda_{\text{surf}} = \int_{\text{surf}} \pi \frac{dB_\nu}{dT} \Big|_{T_s} e^{-\tau_{\text{surf}}} d\nu. \quad (41)$$

631 The column-integrated optical thickness at a single frequency is the sum over all absorbers at
 632 that frequency, $\tau_{\text{surf}}(\nu) = \tau_{\text{H}_2\text{O}}(\nu) + \tau_{\text{CO}_2}(\nu) + \tau_{\text{cnt}}$. However, the optical thickness of H₂O and CO₂
 633 drops off exponentially as a function of wavenumber away from their band centers. Thus most
 634 frequencies are either so optically thick with respect to H₂O and CO₂ that all surface radiation is
 635 absorbed by the atmosphere (and hence does not contribute to the surface feedback), or so optically
 636 thin that we can ignore H₂O and CO₂. Inside the window we therefore only consider absorption
 637 by the grey continuum, $\tau_{\text{surf}} \approx \tau_{\text{cnt}}$, while the H₂O and CO₂ bands primarily set the width of the
 638 window.

639 To determine the width of the window we first consider an atmosphere without CO₂. As discussed
 640 above, in this case the window region is set the H₂O bands, with ν_L denoting the left window edge
 641 around $\sim 700 \text{ cm}^{-1}$ and ν_R the right window edge around $\sim 1200 \text{ cm}^{-1}$. The H₂O continuum is
 642 grey and so can be taken out of the spectral integral,

$$-\lambda_{\text{surf}} \approx e^{-\tau_{\text{cnt}}(T_s)} \int_{\nu_L}^{\nu_R} \pi \frac{dB_\nu}{dT} \Big|_{T_s} d\nu.$$

643 We approximate the integral by treating the Planck function derivative as constant with respect
 644 to wavenumber, evaluated at the central wavenumber $\tilde{\nu}$ of the window region, so $\int dB_\nu/dT d\nu \propto$
 645 $dB_{\tilde{\nu}}/dT \times \Delta\nu$. In reality the Planck derivative is not constant with wavenumber, so our approxima-
 646 tion should only be treated as a scaling which we account for by including a scaling constant c_{surf} .
 647 The magnitude of c_{surf} is further discussed below. The result is

$$-\lambda_{\text{surf}} \approx c_{\text{surf}} \times \pi \frac{dB_{\tilde{\nu}}}{dT} \Big|_{T_s} e^{-\tau_{\text{cnt}}(T_s)} \Delta\nu_{\text{surf}},$$

648 where $\Delta\nu_{\text{surf}} = \nu_R - \nu_L$ is the window region width due to H₂O band absorption (see Eqn. 39), and
 649 we determine the central wavenumber of the window as $\tilde{\nu} = (\nu_R + \nu_L)/2$.

650 Next, we add the effect of CO₂-surface spectral blocking. Even if the atmosphere contained no
 651 water vapor whatsoever, part of the surface's emission would still be absorbed by CO₂ and thus
 652 have no effect on the TOA feedback. We account for the potential overlap between the surface and
 653 CO₂ by simply subtracting the CO₂ band width from the H₂O-only window width,

$$\Delta\tilde{\nu}_{\text{surf}} = \max \left[0, \Delta\nu_{\text{surf}}(T_s, \text{RH}, \gamma_{\text{lr}}) - \Delta\nu_{\text{CO}_2}(q_{\text{CO}_2}) \right], \quad (42)$$

654 where $\Delta\nu_{\text{CO}_2}$ is defined above (Eqn. 36) and the tilde distinguishes the window width here from the
 655 H₂O-only window width. Our final expression for the surface feedback is thus

$$-\lambda_{\text{surf}} \approx c_{\text{surf}} \times \pi \frac{dB_{\tilde{\nu}}}{dT} \Big|_{T_s} e^{-\tau_{\text{cnt}}(T_s)} \Delta\tilde{\nu}_{\text{surf}}. \quad (43)$$

656 *c. H₂O band feedback*

657 The H₂O band feedback is given by

$$-\lambda_{\text{H}_2\text{O}} = \int_{\text{H}_2\text{O}} \pi \frac{dB_{\nu}}{dT} \Big|_{T_{\text{H}_2\text{O}}} \frac{dT_{\text{H}_2\text{O}}}{dT_s} d\nu. \quad (44)$$

658 As sketched in Figure 5, we consider the rotational H₂O band as ranging from $\nu \approx 0$ to the left
 659 edge of the window, ν_L . We do not consider the potential feedback from the vibration-rotation
 660 band at wavenumbers higher than $\sim 1250 \text{ cm}^{-1}$ and, for purposes of the H₂O band feedback, also
 661 ignore CO₂-H₂O overlap effects.

662 The derivative of $T_{\text{H}_2\text{O}}$ can be solved analytically. If water vapor behaved strictly according to
 663 Simpson's law then $dT_{\text{H}_2\text{O}}/dT_s = 0$ and the H₂O band feedback would be zero. Simpson's law is
 664 only an approximation, however, so

$$\begin{aligned} \frac{dT_{\text{H}_2\text{O}}}{dT_s} &= \frac{\partial T_{\text{H}_2\text{O}}}{\partial T_s} + \frac{\partial T_{\text{H}_2\text{O}}}{\partial \gamma_{\text{lr}}} \frac{d\gamma_{\text{lr}}}{dT_s} \\ &= \frac{1}{1 + \gamma_{\text{wv}}\gamma_{\text{lr}}} \frac{T_{\text{H}_2\text{O}}}{T_s} + \\ &\quad \frac{\gamma_{\text{wv}}\gamma_{\text{lr}} - \gamma_{\text{wv}} \log\left(\frac{T_s}{T_0}\right) + \log\left(\frac{1 + \gamma_{\text{wv}}\gamma_{\text{lr}}}{\text{RH}\tau_0^*}\right)}{(1 + \gamma_{\text{wv}}\gamma_{\text{lr}})^2} T_{\text{H}_2\text{O}} \times \frac{d\gamma_{\text{lr}}}{dT_s}. \end{aligned} \quad (45)$$

665 One could also explicitly write out the lapse rate derivative $d\gamma_{\text{lr}}/dT_s$, but the resulting expressions
 666 are long and do not lead to additional physical insight, so in practice we evaluate $d\gamma_{\text{lr}}/dT_s$ numer-
 667 ically. To estimate a typical value for $dT_{\text{H}_2\text{O}}/dT_s$ we ignore lapse rate changes, that is, the second
 668 term in Equation 45. Assuming values representative of Earth's tropics, $1 + \gamma_{\text{wv}}\gamma_{\text{lr}} = 1 + 1/7 \times 20 \sim 4$,
 669 and representative temperatures $T_{\text{H}_2\text{O}} \sim 240 \text{ K}$ (see Figure 4) and $T_s \sim 300 \text{ K}$, a characteristic value

670 for $dT_{\text{H}_2\text{O}}/dT_s$ is thus

$$\frac{dT_{\text{H}_2\text{O}}}{dT_s} \sim \frac{1}{4} \times \frac{240}{300} = \frac{1}{5}, \quad (46)$$

671 in line with the numerical results of Jeevanjee et al. (2021a).

672 Next, we treat the H_2O band feedback similar to the surface feedback. We assume the integrand
673 of the spectral feedback integral is approximately constant with respect to wavenumber, and equal
674 to its value at a central frequency $\tilde{\nu}$. The feedback is then

$$\begin{aligned} -\lambda_{\text{H}_2\text{O}} &= \int_0^{\nu_L} \pi \frac{dB_\nu}{dT} \Big|_{T_{\text{H}_2\text{O}}} \frac{dT_{\text{H}_2\text{O}}}{dT_s} d\nu \\ &\approx c_{\text{H}_2\text{O}} \times \pi \frac{dB_{\tilde{\nu}}}{dT} \Big|_{T_{\text{H}_2\text{O}}(\tilde{\nu})} \times \frac{dT_{\text{H}_2\text{O}}}{dT_s} \Big|_{\tilde{\nu}} \times \Delta\nu_{\text{H}_2\text{O}}, \end{aligned} \quad (47)$$

675 where $\Delta\nu_{\text{H}_2\text{O}} = \nu_L$ is the width of the H_2O band, $\tilde{\nu} = \nu_L/2$ is the central wavenumber of the H_2O
676 band, and $c_{\text{H}_2\text{O}}$ is again a scaling constant to account for the fact that we are replacing a spectral
677 integral with simple multiplication.

678 *d. H₂O continuum feedback*

679 The H_2O continuum feedback is

$$-\lambda_{\text{cnt}} = \int_{\text{cnt}} \pi \frac{dB_\nu}{dT} \Big|_{T_{\text{cnt}}} \frac{dT_{\text{cnt}}}{dT_s} d\nu. \quad (48)$$

680 We apply the same logic as for the surface and H_2O band feedbacks. The derivative dT_{cnt}/dT_s
681 can be solved for analytically: T_{cnt} has no dependence on T_s other than through lapse rate changes,

682 SO

$$\begin{aligned} \frac{dT_{\text{cnt}}}{dT_s} &= \frac{\partial T_{\text{cnt}}}{\partial \gamma_{\text{lr}}} \frac{d\gamma_{\text{lr}}}{dT_s} \\ &= \frac{T_{\text{cnt}}}{\gamma_{\text{lr}}(2\gamma_{\text{wv}} - a)} \frac{d\gamma_{\text{lr}}}{dT_s}. \end{aligned} \quad (49)$$

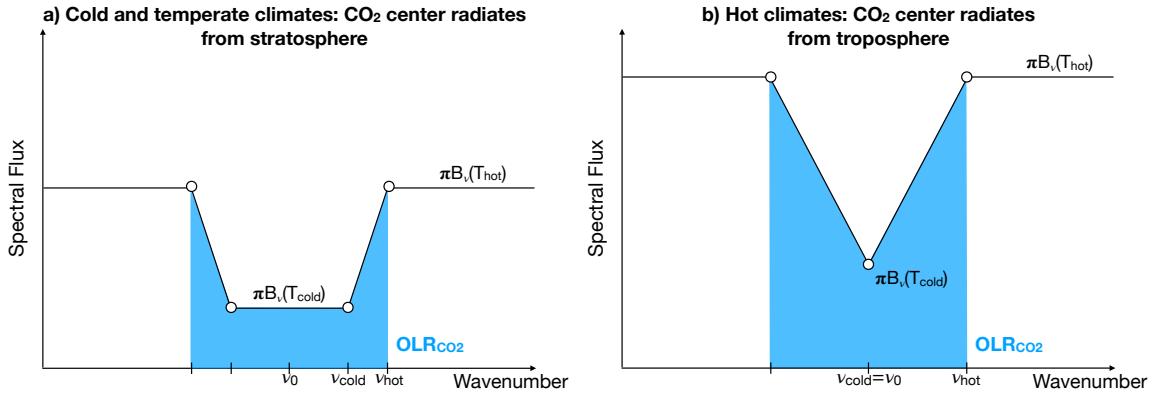

683 One important difference between the continuum and the other feedbacks is that the continuum
684 is transparent across all wavenumbers at low surface temperatures, and only becomes optically

685 thick at high surface temperatures. We approximate the continuum's emissivity as $1 - e^{-\tau_{\text{cnt}}}$, which
 686 correctly captures the limiting behavior of an emitter at small and large optical thickness ($\tau_{\text{cnt}} \ll 1$
 687 versus $\tau_{\text{cnt}} \gg 1$). The continuum can only dominate the atmosphere's emission at wavenumbers at
 688 which CO_2 and H_2O absorption are weak, so we set the effective width of the continuum equal to
 689 the width of the window region $\Delta\tilde{\nu}_{\text{surf}}$, defined above. The continuum feedback is then

$$\begin{aligned}
 -\lambda_{\text{cnt}} &= \int_{\text{cnt}} \pi \frac{dB_\nu}{dT} \Big|_{T_{\text{cnt}}} \frac{dT_{\text{cnt}}}{dT_s} d\nu \\
 &\approx c_{\text{cnt}} \times \pi \frac{dB_{\tilde{\nu}}}{dT} \Big|_{T_{\text{cnt}}} \times \frac{dT_{\text{cnt}}}{dT_s} \times \Delta\tilde{\nu}_{\text{surf}} (1 - e^{-\tau_{\text{cnt}}})
 \end{aligned} \tag{50}$$

690 where c_{cnt} is again a scaling constant. The sign of λ_{cnt} is positive because the bulk lapse rate
 691 decreases with warming, $d\gamma_{\text{lr}}/dT_s < 0$. As discussed above, this means the H_2O continuum acts
 692 as a positive/destabilizing feedback and has the opposite sign of the negative/stabilizing H_2O band
 693 feedback.

694 *e. CO_2 band feedback*

695 FIG. 6. A CO_2 “ditch” model: the CO_2 band emits $\pi B_\nu(T_{\text{cold}})$ in its center, its flanks emit $\pi B_\nu(T_{\text{hot}})$, and the
 696 slopes in-between are approximated as linear and symmetric. Shaded blue area is the OLR contribution from the
 697 CO_2 band. Left: In cold climates or at high CO_2 abundances the CO_2 band center radiates from the stratosphere.
 698 Right: In hot climates or at low CO_2 abundances the CO_2 band center radiates from the troposphere.

699 Next, we consider the CO_2 feedback. Unlike the H_2O band and continuum, however, the emission
 700 temperature of CO_2 varies strongly with wavenumber, which makes it difficult to approximate the

701 CO₂ feedback integral via simple multiplication. Instead we introduce an idealized CO₂ "ditch"
 702 model, illustrated in Figure 6. Our approach is closely related to the CO₂ forcing models of
 703 Wilson and Gea-Banacloche (2012) and Jeevanjee et al. (2021b) – in Appendix A we show that
 704 our ditch model can also be used to rederive the results of those previous studies, underlining the
 705 close relationship between forcing and feedbacks.

706 We approximate the CO₂ band as symmetric around the central frequency $\nu_0 = 667 \text{ cm}^{-1}$. The
 707 center of the band emits $\pi B_\nu(T_{\text{cold}})$ while outside the band the emission is $\pi B_\nu(T_{\text{hot}})$. Here T_{cold}
 708 and T_{hot} are cold and hot emission temperatures, while ν_{hot} and ν_{cold} denote the edges of the CO₂
 709 ditch. At low and moderate surface temperatures the CO₂ band center around 667 cm^{-1} radiates
 710 from the stratosphere, so T_{cold} is equal to the stratospheric temperature. However, this situation
 711 is no longer true at high surface temperatures. Physically, the tropopause rises as the surface
 712 warms, so if one warms the surface while holding CO₂ concentration fixed (this is implicit in the
 713 definition of a climate feedback), parts of the CO₂ band that were previously in the stratosphere
 714 have to start radiating from the troposphere. Eventually, even the CO₂ band center radiates from
 715 the troposphere so the rectangular CO₂ ditch turns into a triangular trough (see Fig. 6b). Here we
 716 leave our expressions general to allow for either situation.

717 The CO₂ band is relatively narrow, so we can neglect the wavenumber-dependence of the Planck
 718 function and evaluate it at the center of the CO₂ band, $\pi B_\nu(T) \approx \pi B_{\nu_0}(T)$. Treating the slopes of
 719 the CO₂ ditch as piecewise-linear, the OLR from the CO₂ band is then simply the blue area under
 720 the ditch in Figure 6a,

$$\begin{aligned} \text{OLR}_{\text{CO}_2} &= 2 \int_{\nu_0}^{\nu_{\text{hot}}} \pi B_{\nu_0}(T_{\text{CO}_2}) d\nu \\ &= [\pi B_{\nu_0}(T_{\text{hot}}) + \pi B_{\nu_0}(T_{\text{cold}})] (\nu_{\text{hot}} - \nu_{\text{cold}}) + 2\pi B_{\nu_0}(T_{\text{cold}})(\nu_{\text{cold}} - \nu_0). \end{aligned} \quad (51)$$

721 The OLR change in response to some climate perturbation is

$$\begin{aligned} \Delta \text{OLR}_{\text{CO}_2} &= \text{OLR}'_{\text{CO}_2} - \text{OLR}_{\text{CO}_2} \\ &= [\pi B_{\nu_0}(T'_{\text{hot}}) + \pi B_{\nu_0}(T'_{\text{cold}})] (\nu'_{\text{hot}} - \nu'_{\text{cold}}) - [\pi B_{\nu_0}(T_{\text{hot}}) + \pi B_{\nu_0}(T_{\text{cold}})] (\nu_{\text{hot}} - \nu_{\text{cold}}) + \\ &\quad 2\pi B_{\nu_0}(T'_{\text{cold}})(\nu'_{\text{cold}} - \nu_0) - 2\pi B_{\nu_0}(T_{\text{cold}})(\nu_{\text{cold}} - \nu_0), \end{aligned} \quad (52)$$

722 where primes indicate perturbed variables. For the CO₂ band feedback the relevant perturbation is
 723 a change in surface temperature ΔT_s , while for the forcing the relevant perturbation is a change in
 724 q_{CO_2} (see Appendix A). If ΔT_s is small enough we can series expand and drop higher-order terms.
 725 For example, the perturbation of the emission at the CO₂ band edge is

$$\pi B_{\nu_0}(T'_{\text{hot}}) = \pi B_{\nu_0}(T_{\text{hot}}) + \pi \left. \frac{dB_{\nu_0}}{dT} \right|_{T_{\text{hot}}} \frac{dT_{\text{hot}}}{dT_s} \Delta T_s,$$

726 with similar expressions for T'_{cold} , ν'_{cold} , and ν'_{cold} . Plugging back into Equation 52, the feedback of
 727 the CO₂ ditch is

$$\begin{aligned} -\lambda_{\text{CO}_2} &= \lim_{\Delta T_s \rightarrow 0} \frac{\Delta \text{OLR}_{\text{CO}_2}}{\Delta T_s} \\ &= \left[\pi \left. \frac{dB_{\nu_0}}{dT} \right|_{T_{\text{hot}}} \frac{dT_{\text{hot}}}{dT_s} + \pi \left. \frac{dB_{\nu_0}}{dT} \right|_{T_{\text{cold}}} \frac{dT_{\text{cold}}}{dT_s} \right] (\nu_{\text{hot}} - \nu_{\text{cold}}) \\ &\quad + [\pi B_{\nu_0}(T_{\text{hot}}) + \pi B_{\nu_0}(T_{\text{cold}})] \left(\frac{d\nu_{\text{hot}}}{dT_s} - \frac{d\nu_{\text{cold}}}{dT_s} \right) \\ &\quad + 2 \pi \left. \frac{dB_{\nu_0}}{dT} \right|_{T_{\text{cold}}} \frac{dT_{\text{cold}}}{dT_s} (\nu_{\text{cold}} - \nu_0) + 2 B_{\nu_0}(T_{\text{cold}}) \frac{d\nu_{\text{cold}}}{dT_s}. \end{aligned} \quad (53)$$

728 Equation 53 gives the most general expression for the feedback of the CO₂ ditch. Geometrically,
 729 the blue area under the CO₂ ditch changes if the flanks and center rise while the edges remain fixed
 730 (terms proportional to dT_{hot}/dT_s and dT_{cold}/dT_s), or if the edges move while the flanks and center
 731 of the ditch remain fixed (terms proportional to $d\nu_{\text{hot}}/dT_s$ and $d\nu_{\text{cold}}/dT_s$). To evaluate Equation
 732 53 we thus need to specify how the parameters T_{hot} , T_{cold} , ν_{hot} and ν_{cold} vary as a function of
 733 surface temperature.

734 At cold surface temperatures we again ignore H₂O absorption around the CO₂ band so $T_{\text{hot}} = T_s$.
 735 Similarly, the tropopause is low and the CO₂ band center radiates from the stratosphere, so
 736 $T_{\text{cold}} = T_{\text{strat}}$ and $dT_{\text{cold}}/dT_s = 0$. As in Section 5a, we find the band edges ν_{hot} and ν_{cold} by
 737 solving $T_{\text{CO}_2}(\nu_{\text{hot}}) = T_s$ and $T_{\text{CO}_2}(\nu_{\text{cold}}) = T_{\text{strat}}$. The results are $\nu_{\text{hot}} = \nu_0 + l_\nu \log[\tau_{\text{CO}_2}^*(\nu_0) q_{\text{CO}_2}]$, and
 738 $\nu_{\text{cold}} = \nu_0 + l_\nu \log[\tau_{\text{CO}_2}^*(\nu_0) q_{\text{CO}_2} (T_{\text{strat}}/T_s)^{2/\gamma_{\text{tr}}}]$. We can see that the hot CO₂ band edge does not
 739 change under surface warming, $d\nu_{\text{hot}}/dT_s = 0$, while the sensitivity of the cold or stratospheric

740 band edge to surface warming is

$$\begin{aligned}
 \frac{d\nu_{\text{cold}}}{dT_s} &= \left. \frac{\partial \nu_{\text{cold}}}{\partial T_s} \right|_{\gamma_{\text{lr}}} + \left. \frac{\partial \nu_{\text{cold}}}{\partial \gamma_{\text{lr}}} \right|_{T_s} \frac{d\gamma_{\text{lr}}}{dT_s} \\
 &= -\frac{2l_\nu}{\gamma_{\text{lr}} T_s} + \frac{2l_\nu}{\gamma_{\text{lr}}^2} \log\left(\frac{T_s}{T_{\text{strat}}}\right) \frac{d\gamma_{\text{lr}}}{dT_s}.
 \end{aligned} \tag{54}$$

741 The lapse rate change $d\gamma_{\text{lr}}/dT_s$ is always negative, so the portion of the CO₂ band inside the
 742 stratosphere shrinks, $d\nu_{\text{cold}}/dT_s < 0$. Geometrically, since ν_{hot} stays fixed while ν_{cold} moves
 743 towards the center of the CO₂ band, the CO₂ band slope becomes shallower and the blue area
 744 under the CO₂ ditch increases – an OLR increase, or a stabilizing feedback. Physically, this is
 745 a simple consequence of a rising tropopause. As the surface warms, the tropopause moves to
 746 lower pressures, thus moving more of CO₂'s emission from the cold stratosphere into the warmer
 747 tropopause. Plugging back into Equation 53, the CO₂ band feedback at cold surface temperatures
 748 is

$$\begin{aligned}
 -\lambda_{\text{CO}_2}^{\text{cool}} &= \pi \left. \frac{dB_{\nu_0}}{dT} \right|_{T_s} \frac{2}{\gamma_{\text{lr}}} \log\left(\frac{T_s}{T_{\text{strat}}}\right) + \left[\pi B_{\nu_0}(T_s) - \pi B_{\nu_0}(T_{\text{strat}}) \right] \\
 &\quad \times \left(\frac{2l_\nu}{\gamma_{\text{lr}} T_s} - \frac{2l_\nu}{\gamma_{\text{lr}}^2} \log\left(\frac{T_s}{T_{\text{strat}}}\right) \frac{d\gamma_{\text{lr}}}{dT_s} \right)
 \end{aligned} \tag{55}$$

749 At high surface temperatures the CO₂ band center moves into the tropopause and the rectangular
 750 ditch turns into a triangle (see lower left in Fig. 4, and sketch in Fig. 6b). We set $\nu_{\text{cold}} = \nu_0$,
 751 where the central wavenumber ν_0 is set by the spectroscopic properties of CO₂ and so is fixed
 752 under surface warming ($d\nu_{\text{cold}}/dT_s = 0$). The emission temperature in the center of the CO₂ band
 753 is now $T_{\text{cold}} = T_{\text{CO}_2}(\nu_0)$, where T_{CO_2} is the emission temperature of CO₂ (Eqn. 26a). The crucial
 754 difference between high and low surface temperatures is that once the CO₂ band center moves into
 755 the tropopause T_{cold} is no longer constant,

$$\begin{aligned}
 \frac{dT_{\text{CO}_2}(\nu_0)}{dT_s} &= \left. \frac{\partial T_{\text{CO}_2}(\nu_0)}{\partial T_s} \right|_{\gamma_{\text{lr}}} + \left. \frac{\partial T_{\text{CO}_2}(\nu_0)}{\partial \gamma_{\text{lr}}} \right|_{T_s} \frac{d\gamma_{\text{lr}}}{dT_s} \\
 &= \frac{T_{\text{CO}_2}(\nu_0)}{T_s} - \frac{T_{\text{CO}_2}(\nu_0)}{2} \log[q_{\text{CO}_2} \tau_{\text{CO}_2}^*(\nu_0)] \frac{d\gamma_{\text{lr}}}{dT_s}.
 \end{aligned} \tag{56}$$

756 The outer edges of the CO₂ band at high temperatures are set by water vapor absorption,
 757 $T_{\text{hot}} = \min[T_{\text{H}_2\text{O}}(\nu_0), T_{\text{cnt}}]$. We treat H₂O as Simpsonian, so $dT_{\text{hot}}/dT_s \approx 0$, and also ignore non-
 758 Simpsonian shifts in the outer CO₂ band edge, $d\nu_{\text{hot}}/dT_s \approx 0$. Plugging back into Equation 53, the
 759 feedback at high surface temperatures is then

$$\begin{aligned}
 -\lambda_{\text{CO}_2}^{\text{hot}} &= \pi \left. \frac{dB_{\nu_0}}{dT} \right|_{T_{\text{cold}}} \frac{dT_{\text{cold}}}{dT_s} (\nu_{\text{hot}} - \nu_{\text{cold}}) \\
 &= \pi \left. \frac{dB_{\nu_0}}{dT} \right|_{T_{\text{cold}}} \frac{dT_{\text{cold}}}{dT_s} l_{\nu} \log \left[\tau_{\text{CO}_2}^*(\nu_0) q_{\text{CO}_2} \left(\frac{T_{\text{hot}}}{T_s} \right)^{\frac{2}{\gamma_{\text{tr}}}} \right].
 \end{aligned} \tag{57}$$

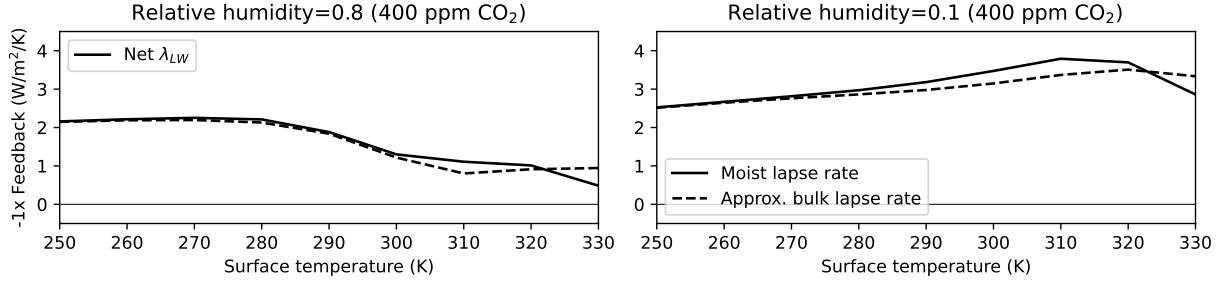

760 Geometrically, the behavior of the CO₂ band at high temperatures is dictated by the rise in the
 761 center of the band, dT_{cold}/dT_s . Since the band center emits more in response to surface warming,
 762 $dT_{\text{cold}}/dT_s > 0$, the blue area under the triangular ditch goes up – again, an OLR increase, which
 763 leads to a stabilizing feedback. Physically, once the center of the CO₂ band radiates from inside the
 764 troposphere, we have $dT_{\text{cold}}/dT_s \propto -d\gamma_{\text{tr}}/dT_s$, which means the rate at which emission increases
 765 is highly sensitive to the rate at which the upper atmosphere warms via the changing lapse rate.

766 Finally, when does the CO₂ band center change from a stratospheric radiator at low T_s to a
 767 tropospheric radiator at high T_s , which also determines the transition between $\lambda_{\text{CO}_2}^{\text{cool}}$ and $\lambda_{\text{CO}_2}^{\text{hot}}$?
 768 Based on line-by-line calculations with 400 ppm of CO₂, Appendix B shows that the smoothed
 769 emission temperature in the CO₂ band center moves out of the stratosphere at surface temperatures
 770 above 310 K. We therefore identify 310 K as the transition point between the low-temperature
 771 and high-temperature CO₂ feedback regimes. Note, however, that this value also depends on CO₂
 772 concentration.

773 Multiplying the low-temperature regime with a scaling constant c_{CO_2} , similar to our other spectral
 774 feedbacks, the overall CO₂ band feedback is thus

$$\lambda_{\text{CO}_2} = \begin{cases} c_{\text{CO}_2} \times \lambda_{\text{CO}_2}^{\text{cool}} & \text{if } T_s \leq 310 \text{ K} \\ \lambda_{\text{CO}_2}^{\text{hot}} + b & \text{if } T_s > 310 \text{ K.} \end{cases} \tag{58}$$

775 where we choose the constant b to ensure that λ_{CO_2} remains continuous at 310 K (in practice b is
 776 always of order unity, $b \sim 0.5$).

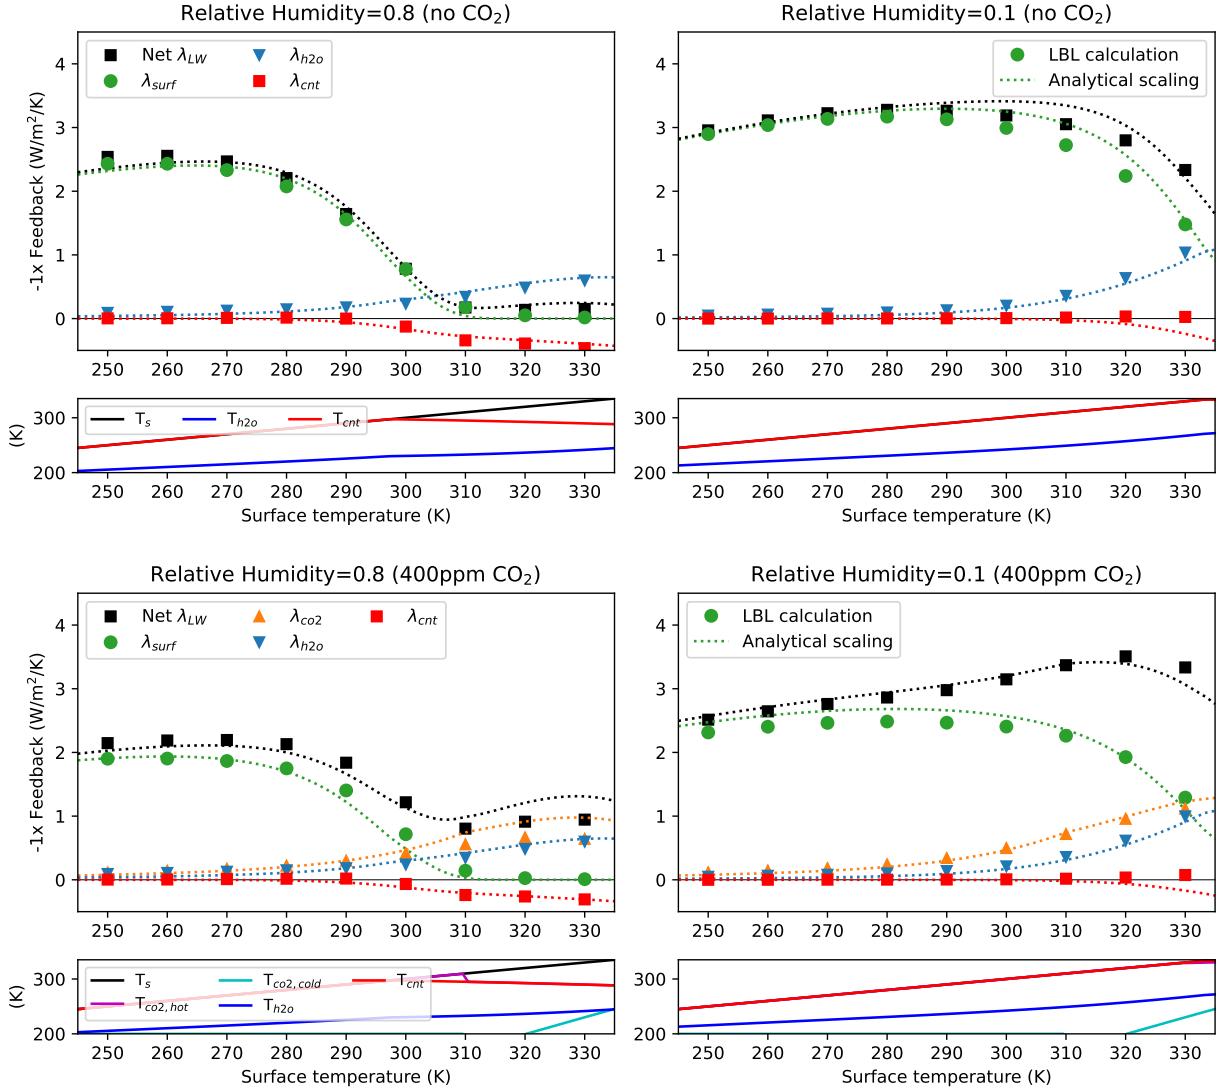

778 FIG. 7. The impact of the bulk lapse rate approximation on longwave feedbacks is modest below ~ 320 K,
 779 but becomes significant at high temperatures. Solid lines are numerical feedbacks calculated assuming the
 780 atmosphere follows a moist adiabatic profile, dashed lines are numerical feedbacks calculated assuming the
 781 atmosphere follows our bulk lapse rate approximation.

777 *f. Validation against LBL calculations*

782 To test our analytic feedback expressions we again use 1D calculations with PyRADS. One
 783 potential issue is that our derivations use the bulk lapse rate approximation, and so might differ
 784 from realistic feedbacks. Figure 7 compares feedbacks calculated with a moist adiabat to feedbacks
 785 with bulk lapse rate profiles. Overall, the bulk lapse rate approximation only introduces minor
 786 errors in λ_{LW} over the temperature range 250 – 320 K. We therefore consider the bulk lapse
 787 rate approximation sufficiently accurate below 320 K, while care should be taken when applying
 788 our analytic expressions to extremely hot climates. To better match the derivations, the PyRADS
 789 calculations here also use vertical profiles with a bulk lapse rate, so $T = T_s (p/p_s)^{\gamma_{lr}}$. We explore the
 790 surface temperature-dependence of spectral feedbacks at high and low relative humidity (RH=0.8
 791 and RH=0.1), without CO₂ and with 400 ppm of CO₂, for four sets of calculations in total.

792 To compare our analytic expressions against the 1D calculations we need to specify the scaling
 793 constants c_{surf} , $c_{\text{H}_2\text{O}}$, c_{cnt} , and c_{CO_2} . We pick these constants to match the 1D calculations at
 794 RH=0.8 and 400 ppm of CO₂. The temperature-dependence varies significantly between different
 795 feedbacks, so we choose c_{surf} to match λ_{surf} at low temperatures ($T_s = 250$ K), c_{cnt} to match λ_{cnt}
 796 at high temperatures ($T_s = 330$ K), and $c_{\text{H}_2\text{O}}$ and c_{CO_2} to match $\lambda_{\text{H}_2\text{O}}$ and λ_{CO_2} around Earth’s
 797 present-day mean temperature ($T_s = 290$ K). Table 1 gives the resulting values for the above 1D
 798 calculations with bulk lapse rates, and for another set of 1D calculations with moist lapse rates.
 799 In agreement with Figure 7, the scaling constants vary little between the two sets of calculations.

800 In this Section we choose the scaling constants to match the idealized 1D calculations with bulk
 801 lapse rates, while Section 6 considers a feedback calculation specifically for present-day Earth, and
 802 so uses the scaling constants that match the moist adiabatic calculations. Regardless of the exact
 803 values, the scaling constants are always of order unity.

804 FIG. 8. Spectral feedbacks calculated using PyRADs and assuming a bulk lapse rate (symbols), compared
 805 against the analytic scalings (lines). Top row shows calculations without CO₂, bottom row with 400ppm of CO₂.
 806 The large panels show feedbacks while small panels show the corresponding analytic emission temperatures.

807 Figure 8 shows that our analytic expressions successfully capture the basic state-dependence of
 808 λ_{LW} as well as of its spectral constituents. The longwave feedback λ_{LW} is sensitive to changes in

809 surface temperature, but it also varies in response to humidity and CO₂ changes. Comparing the
810 left and right columns in Figure 8, λ_{LW} becomes larger with decreasing relative humidity (also see
811 McKim et al. 2021). Comparing the top and bottom rows, adding CO₂ to an atmosphere without
812 any CO₂ evens out the temperature-dependence of λ_{LW} , by decreasing λ_{LW} at cold temperatures
813 and increasing λ_{LW} at high temperatures. Importantly, the analytic expressions capture most of the
814 variation in λ_{LW} , including its state-dependence.

815 To understand the behavior of λ_{LW} we turn to the individual spectral feedbacks. The surface
816 feedback λ_{surf} is generally the dominant term in the spectral decomposition. Without CO₂, λ_{surf}
817 makes up at least 90% of λ_{LW} below 300 K. The presence of CO₂ decreases λ_{surf} but even in this
818 case λ_{surf} makes up at least 60% of λ_{LW} below 300 K. Our analytic expressions thus agree with
819 previous studies which showed that Earth’s longwave feedback is dominated by the surface feedback
820 (Koll and Cronin 2018; Raghuraman et al. 2019). This situation changes at high temperatures,
821 however, once the surface window closes, at which point λ_{LW} becomes dominated by atmospheric
822 feedbacks.

823 In line with Section 4, the CO₂ band feedback acts to stabilize Earth’s climate in warm climates,
824 and its importance increases with surface temperature. Below 300 K, λ_{CO_2} contributes less than
825 20% of the total feedback, but its magnitude grows rapidly with surface temperature such that at
826 330 K and high relative humidity λ_{CO_2} makes up almost 70% of λ_{LW} . Interestingly, for large RH
827 λ_{CO_2} becomes equal to λ_{surf} at surface temperatures around ~ 305 K. Extrapolating from these 1D
828 calculations to Earth’s spatial feedback pattern, we can expect that Earth’s feedback is dominated
829 by the surface in most regions, but that atmospheric feedbacks become important in the inner
830 tropics – an issue explored in detail in Section 6.

831 Finally, again in line with our analytic results, the two water vapor feedbacks $\lambda_{\text{H}_2\text{O}}$ and λ_{cnt}
832 have opposing signs. At high relative humidity $\lambda_{\text{H}_2\text{O}}$ and λ_{cnt} partially cancel. In contrast, at low
833 relative humidity λ_{cnt} becomes negligible while $\lambda_{\text{H}_2\text{O}}$ only changes moderately – a non-Simpsonian
834 effect. The different sensitivity to RH arises because the continuum’s optical thickness scales as
835 $\tau_{\text{cnt}} \propto \text{RH}^2$, whereas the optical thickness in the water vapor bands only scales as $\tau_{\text{H}_2\text{O}} \propto \text{RH}$.
836 Decreases in relative humidity therefore increase λ_{LW} both by increasing the surface feedback λ_{surf}
837 and by reducing λ_{cnt} , so that H₂O acts as a net stabilizing feedback. Comparing $\lambda_{\text{H}_2\text{O}}$ and λ_{CO_2}
838 at present-day CO₂ levels, we see that the two feedbacks are roughly equal in magnitude. Non-

TABLE 2. Summary of main theoretical results.

Emission temperatures

$-\lambda_{\text{H}_2\text{O}} =$	$c_{\text{H}_2\text{O}} \times \pi \frac{dB_{\tilde{\nu}}}{dT} \Big _{T_{\text{H}_2\text{O}}(\tilde{\nu})} \times \frac{dT_{\text{H}_2\text{O}}(\tilde{\nu})}{dT_s} \times \Delta\nu_{\text{H}_2\text{O}}$
$-\lambda_{\text{cnt}} =$	$c_{\text{cnt}} \times \pi \frac{dB_{\tilde{\nu}}}{dT} \Big _{\tilde{\nu}, T_{\text{cnt}}} \times \frac{dT_{\text{cnt}}}{dT_s} \times \Delta\tilde{\nu}_{\text{surf}} (1 - e^{-\tau_{\text{cnt}}})$
$-\lambda_{\text{CO}_2} =$	$\begin{cases} c_{\text{CO}_2} \times \frac{2\pi}{\gamma_{\text{lr}}} \frac{dB_{\nu_0}}{dT} \Big _{T_s} \log\left(\frac{T_s}{T_{\text{strat}}}\right) - [\pi B_{\nu_0}(T_s) - \pi B_{\nu_0}(T_{\text{strat}})] \times \frac{d\nu_{\text{cold}}}{dT_s} & \text{at low } T_s \\ \pi \frac{dB_{\nu_0}}{dT} \Big _{T_{\text{cold}}} \frac{dT_{\text{cold}}}{dT_s} (\nu_{\text{hot}} - \nu_{\text{cold}}) + b & \text{at high } T_s \end{cases}$

839 Simpsonian H₂O effects are thus about as important as the CO₂ band for Earth's current longwave
840 feedback.

841 6. The Spatial Pattern of λ_{LW}

842 In the previous two sections we demonstrated that the analytic expressions summarized in Table 2
843 accurately capture the behavior of Earth's emission temperature T_{rad} as well as the state-dependence
844 of λ_{LW} . These feedback expressions can be interpreted as either a model for the global-mean feedback
845 or as a model for the local feedback of an isolated atmospheric column, so the state-dependence of
846 λ_{LW} shown in Figure 8 should also appear as a spatial-dependence in Earth's clear-sky longwave
847 feedback.

848 In this section we therefore analyze the spatial pattern of λ_{LW} for Earth's present-day climate.
849 First, we generate a map of λ_{LW} using the radiative kernel technique (Soden et al. 2008). Next,
850 we generate a map of λ_{LW} using our analytic expressions. The radiative kernel technique cannot
851 be used to determine the feedback contributions of individual gases and our analytic expressions
852 only account for the feedback from Earth's dominant greenhouse gases, H₂O and CO₂, whereas
853 the radiative kernel includes additional greenhouse gases such as O₃ and CH₄. We therefore

854 split λ_{LW} into only two terms, namely the surface feedback λ_{surf} and the atmospheric feedback
855 $\lambda_{atm} = \lambda_{LW} - \lambda_{surf}$. Despite the idealizations in our analytic approach compared to a full radiative
856 kernel, we find that the resulting feedback maps are in qualitative agreement. This allows us to
857 attribute the spatial pattern of λ_{LW} , as deduced from the radiative kernel, to geographic variations
858 in the inputs of our analytic model.

859 *a. Inputs for feedback maps*

860 For the kernel calculation we use the HadGEM2 radiative kernel. For consistency with the
861 analytic model (which assumes the stratosphere is isothermal and at a fixed temperature), we set
862 the kernel to zero in the stratosphere. The tropopause is defined as in Soden et al. (2008): the
863 tropopause pressure p_{tp} increases linearly with latitude, from 0.1 bar at the equator to 0.3 bar at the
864 poles. The analytic model also assumes RH stays fixed under surface warming, so we do not include
865 RH changes in the kernel calculation. Doing so is justified because the RH feedback only makes a
866 minor contribution to λ_{LW} in individual climate models, and it moreover tends to cancel in the multi-
867 model mean (Zelinka et al. 2020). To compute the forced response we use HadGEM2 climatologies
868 from the CMIP5 archive for a preindustrial control simulation and an abrupt-4xCO₂ simulation,
869 where the climatologies are 50-year averages (for 4xCO₂, years 100-150 after increasing CO₂).
870 Multiplying the kernel with the forced response gives a map of the change in top-of-atmosphere
871 (TOA) radiation (Soden et al. 2008). To compute a feedback one additionally needs to normalize
872 the change in TOA radiation by a change in surface temperature. Consistent with our assumption
873 of an isolated atmospheric column we compute local-local feedback maps, that is, we divide the
874 local change in OLR deduced from the kernel by the local change in surface temperature (Feldl
875 and Roe 2013; Armour et al. 2013; Bloch-Johnson et al. 2020). To distinguish between surface
876 and atmospheric feedbacks in the kernel method we compute the clear-sky longwave feedback λ_{LW}
877 and the surface feedback λ_{surf} , where the second is equal to the surface kernel; the atmospheric
878 feedback is then computed as the residual $\lambda_{atm} = \lambda_{LW} - \lambda_{surf}$.

879 We compare the kernel-derived feedback maps against maps from our analytic expressions. The
880 surface feedback λ_{surf} is the same as in Section 5, while the atmospheric feedback is the sum over all
881 atmospheric terms $\lambda_{atm} = \lambda_{CO_2} + \lambda_{H_2O} + \lambda_{cnt}$. The analytic expressions require six input parameters:
882 CO₂ concentration, surface temperature T_s , stratosphere temperature T_{strat} , relative humidity RH,

883 temperature lapse rate γ_{lr} , and the change in lapse rate under surface warming $d\gamma_{lr}/dT_s$. Except for
884 the lapse rate change $d\gamma_{lr}/dT_s$, all these inputs can be obtained from a single climate state (here, the
885 HadGEM2 preindustrial state) and do not require knowledge of the climate's forced response. CO₂
886 is set to be spatially uniform at 400 ppm (results are highly similar if using a preindustrial 285 ppm);
887 the surface temperature T_s is taken as the air temperature at 2m; and the stratospheric temperature
888 T_{strat} is set equal to the temperature at the tropopause pressure level, $T_{strat} = T(p_{tp})$, where p_{tp} is
889 defined using via the above tropopause definition of Soden et al. (2008). The relative humidity RH
890 is set equal to the column relative humidity, defined as the ratio between the atmospheric column's
891 water vapor path and its water vapor path at saturation (e.g., Bretherton et al. 2005),

$$\text{RH} = \frac{\text{WVP}}{\text{WVP}^*}, \quad (59)$$

$$= \frac{\int_{p_{tp}}^{p_s} q \, dp/g}{\int_{p_{tp}}^{p_s} q^* \, dp/g}. \quad (60)$$

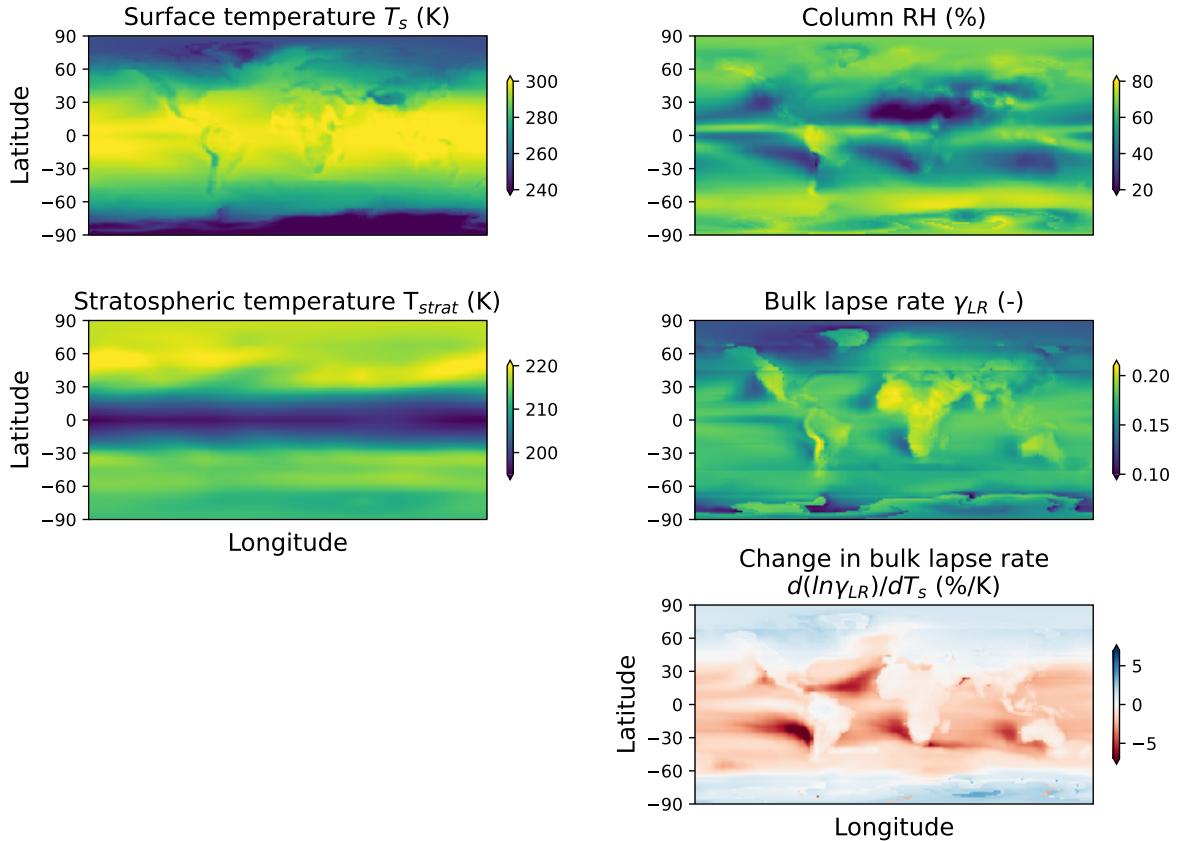

892 Here the vertical integral is taken from the tropopause p_{tp} down to the surface to exclude the
893 strongly sub-saturated stratosphere. One could in principle also approximate RH using other
894 measures of atmospheric humidity; however, the column relative humidity is a natural choice
895 because it correctly captures the atmosphere's total water vapor path, which in turn determines the
896 width of the window region and λ_{surf} .

897 Next, the lapse rate $\gamma_{lr} = d\ln T/d\ln p$ varies strongly in the vertical. We compute a bulk lapse
898 rate using a mass-weighted vertical average,

$$\gamma_{lr} = \frac{1}{p_1 - p_{tp}} \int_{p_{tp}}^{p_1} \frac{p}{T} \frac{dT}{dp} dp, \quad (61)$$

899 where the average is taken from the tropopause p_{tp} down to a near-surface pressure p_1 . Some polar
900 regions have such strong surface inversions that the inferred bulk lapse rate becomes negative,
901 whereas our derivations break down if $\gamma_{lr} < 0$. At the same time, the map of γ_{lr} should reflect near-
902 surface inversions over subtropical eastern ocean basins and deep boundary layers over tropical
903 land, discussed below. We therefore define p_1 similar to p_{tp} , as varying linearly in latitude from
904 $p_1 = 1$ bar at the equator to $p_1 = 0.85$ bar at the poles. One could also evaluate γ_{lr} using the
905 bulk lapse rate definition from Equation 6 in combination with a tropopause definition; however,

906 this approach makes the inferred lapse rates quite sensitive to the tropopause definition, which we
 907 side-step by using the mass-weighted average in Equation 61 instead. Finally, the only input in our
 908 analytic expressions that requires information about the climate’s forced response is the change in
 909 lapse rate $d\gamma_{lr}/dT_s$, which is computed using the difference in γ_{lr} between the HadGEM2 4xCO₂
 910 and preindustrial simulations.

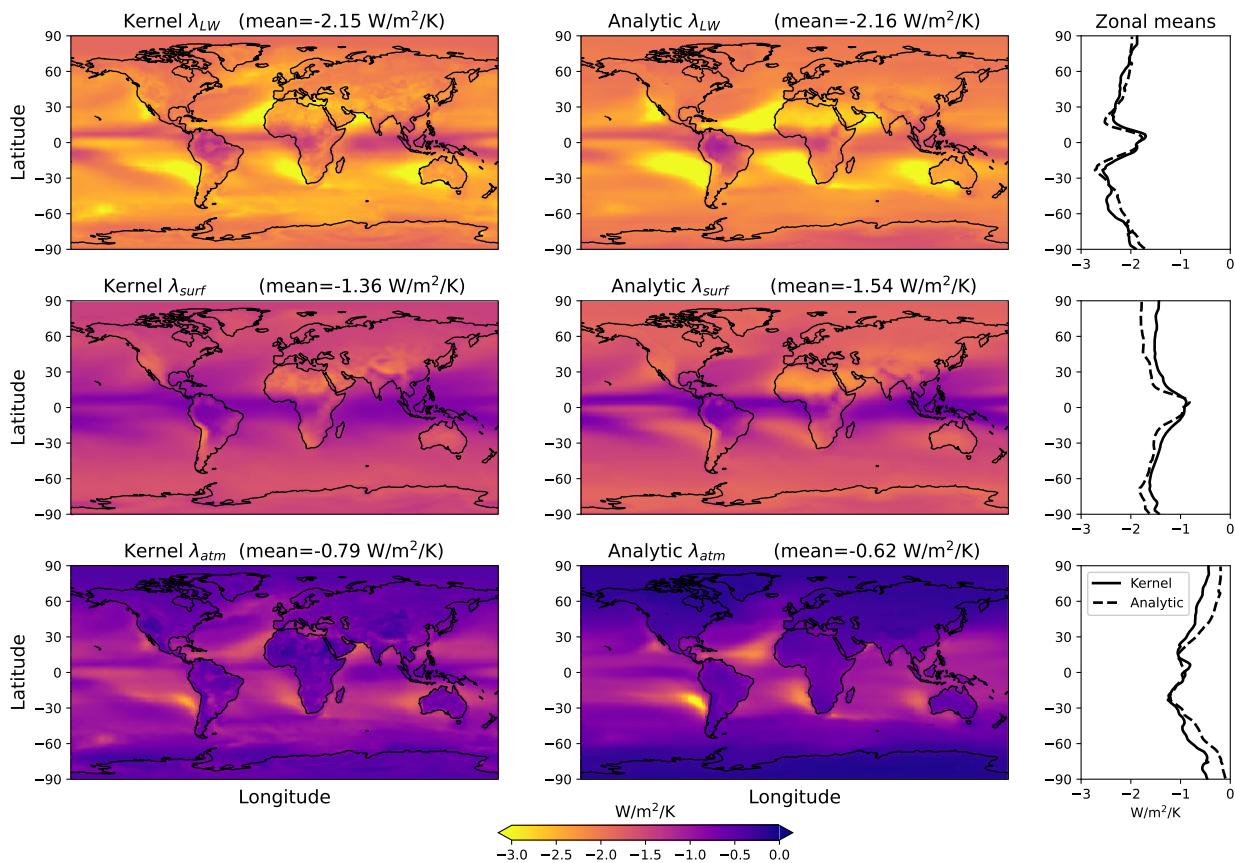

911 FIG. 9. Input data used to evaluate the analytic feedback maps in Figure 10. The top four panels show fields
 912 from a HadGEM2 preindustrial simulation. The bottom right panel shows the normalized bulk lapse rate change
 913 $d\ln(\gamma_{lr})/dT_s$ computed using the HadGEM2 4xCO₂ and preindustrial simulations.

914 Figure 9 shows maps of the input data from HadGEM2, which we use below to evaluate the
 915 analytic expressions. In the top two rows, large variations are notable in the maps of surface
 916 temperature T_s , column relative humidity RH, and bulk lapse rate γ_{lr} . In contrast, apart from minor
 917 stationary wave patterns in the northern mid-latitudes, the stratospheric temperature T_{strat} is zonally
 918 fairly uniform and varies by only about 20 K between the equator and poles. The bottom row

919 shows the normalized bulk lapse change, $d\ln(\gamma_{lr})/dT_s = 1/(\Delta\gamma_{lr}) \times (\Delta\gamma_{lr}/\Delta T_s)$, computed using
920 the bulk lapse rate difference $\Delta\gamma_{lr}$ between 4xCO₂ and preindustrial simulations. The bulk lapse
921 rate change shows an equator-pole contrast, with a decrease in γ_{lr} at low and mid latitudes and
922 an increase in γ_{lr} at high latitudes. This contrast is in line with previous studies – for a moist
923 adiabat the atmospheric temperature-pressure profile becomes less steep under warming, so γ_{lr}
924 decreases in the tropics, while the opposite occurs at high latitudes (e.g., Payne et al. 2015; Cronin
925 and Jansen 2016; Stuecker et al. 2018). There is also a noticeable tropical land-ocean contrast in
926 the bulk lapse-rate change, with tropical land areas showing near-zero lapse-rate change. This is
927 likely due to compensation between moist-adiabatic warming aloft, which is uniform across the
928 tropics and tends to decrease γ_{lr} , and amplified land surface warming, which increases γ_{lr} (Byrne
929 and O’Gorman 2013). Conversely, subtropical eastern ocean basins have the same moist adiabatic
930 warming aloft but *suppressed* surface warming, both of which contribute to strong decreases in γ_{lr} .

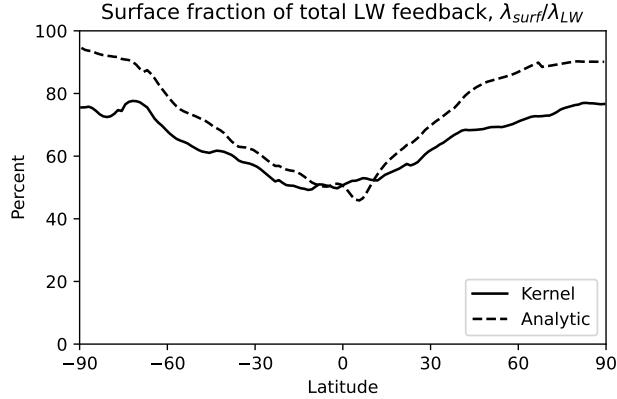

931 *b. Feedback maps*

937 Figure 10 shows the feedback maps resulting from kernel and analytic calculations. Overall, we
938 find good qualitative agreement between kernel-derived feedbacks and our analytic approximations.
939 The global pattern of λ_{LW} in both maps shows clear contrasts between the high latitudes, subtropics,
940 and inner tropics (Fig. 10, top row). λ_{LW} is smallest in the inner tropics, especially in the
941 intertropical convergence zone (ITCZ), while it is largest in the subtropics, especially over eastern
942 ocean basins. The agreement is less good at small scales, with the analytic map of λ_{LW} showing
943 less regional structure and deviating from the kernel-derived map in continental interiors and
944 over the Southern Ocean. This is plausible given the idealizations in our derivations, such as
945 representing realistic vertical temperature profiles by a smooth power-law. However, small-scale
946 differences tend to cancel when taking a zonal or global mean. The zonal-mean of λ_{LW} in our
947 analytic estimate agrees with the zonal-mean of the kernel λ_{LW} to within 11% at each latitude. The
948 global-mean values of λ_{LW} are almost identical, with -2.15 W/m²/K for the kernel calculation and
949 -2.16 W/m²/K for the analytic estimate. Note that these global mean averages are weighted by the
950 HadGEM2 pattern of surface warming, which is required to convert a local-local feedback map
951 into a global mean (Feldl and Roe 2013; Armour et al. 2013).

932 FIG. 10. Feedback maps showing feedbacks computed with a radiative kernel (left column), or with our analytic
 933 expressions (middle column). The analytic maps are calculated from the inputs shown in Figure 9. Top row
 934 shows the net longwave clear-sky feedback λ_{LW} , middle row the surface component λ_{surf} , and bottom row and
 935 the atmospheric component λ_{atm} . Means above each subpanel are area-weighted global means that are weighted
 936 by the pattern of surface warming.

952 The qualitative agreement between the λ_{LW} maps also holds separately for surface and atmo-
 953 spheric feedbacks, though differences are larger here. The kernel-derived map of λ_{surf} is almost
 954 uniform at high latitudes, large in magnitude over subtropical desert regions, and small in magnitude
 955 over the ITCZ. The analytic map of λ_{surf} qualitatively matches this pattern, though it overpredicts
 956 the magnitude of λ_{surf} in the global mean by $0.18 W/m^2/K$, or 13%. Conversely, the analytic esti-
 957 mate underpredicts λ_{atm} relative to the kernel-derived map in the global mean by $0.17 W/m^2/K$, or
 958 22%. In addition, the analytic λ_{atm} map predicts that the atmospheric feedback goes almost to zero
 959 at the poles, whereas the kernel-derived λ_{atm} map shows a small but clearly non-zero feedback. The
 960 strong differences at the poles again presumably arise because our derivations fail to capture the

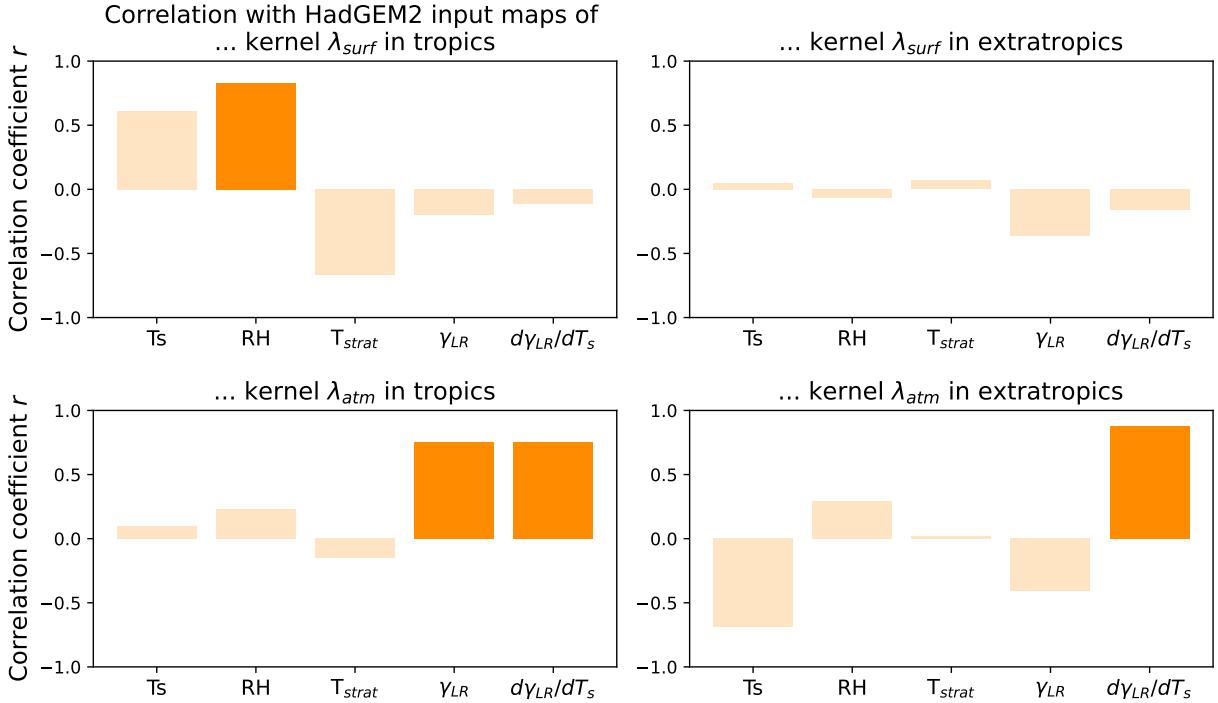

963 FIG. 11. Zonal mean fraction of the surface feedback to the net feedback, $\lambda_{\text{surf}}/\lambda_{LW}$, based on the radiative
 964 kernel (solid) and our analytic expressions (dashed).

961 atmospheric feedback response in areas with inversions and other complex temperature-pressure
 962 profiles.

965 In addition to an overall spatial agreement, both kernel and analytic feedback calculations
 966 agree that the surface dominates the net longwave feedback. Figure 11 shows that the surface's
 967 contribution to the total feedback is about 50% at low latitudes and increases towards the poles,
 968 reaching about 75% in the kernel maps and over 90% in the analytic maps. One plausible reason
 969 why the analytic maps tend to overestimate $\lambda_{\text{surf}}/\lambda_{LW}$ at high latitudes is that our expressions do not
 970 include minor greenhouse gases such as ozone or methane. Any additional atmospheric absorption
 971 from such gases reduces the window width via $\Delta\nu_{\text{surf}} \times e^{-\tau_{\text{cnt}}}$ and thus also the surface feedback λ_{surf}
 972 (also see Feng et al. 2022). This effect should be most clearly visible at high latitudes, where water
 973 vapor concentrations are low and $\Delta\nu_{\text{surf}}$ is large, while at low latitudes $\Delta\nu_{\text{surf}} \times e^{-\tau_{\text{cnt}}}$ is already
 974 small due to the water vapor continuum, leaving less room for other greenhouse gases to affect
 975 λ_{surf} . Nevertheless, in line with the results from Section 5, both kernel and analytic maps show
 976 that λ_{LW} is dominated by λ_{surf} across most of the globe. In contrast, atmospheric feedbacks only
 977 start to rival λ_{surf} in the inner tropics and particularly inside the ITCZ (Fig. 10). Our finding agrees
 978 with other published estimates: the simple area-weighted global mean of $\lambda_{\text{surf}}/\lambda_{LW}$ is 60% in our
 979 kernel calculation and 67% in our analytic estimate, well in line with the results of Raghuraman
 980 et al. (2019) who deduced 63% using a different methodology. Similarly, Feng et al. (2022) found
 981 that $\lambda_{\text{surf}}/\lambda_{LW}$ varies between 88% at the poles to 50% in the tropics, in good agreement with

982 Figure 11. We conclude that our analytic model of λ_{LW} has notable biases at regional scales but it
 983 is sufficient to understand the factors that underlie the large-scale pattern of λ_{LW} , which we turn to
 984 next.

985 *c. What controls the large-scale pattern of λ_{LW} ?*

986 FIG. 12. Spatial correlation between the kernel-derived feedback maps of λ_{surf} and λ_{atm} (Figure 10, left
 987 column), and the inputs to our analytic model (Figure 9). Top row shows correlations between inputs and λ_{surf} ,
 988 bottom row shows correlations between inputs and λ_{atm} . Left column shows correlations inside the tropics, right
 989 column shows correlations in the extratropics. Dark colors highlight particularly strong correlations ($|r| \geq 0.75$),
 990 while the tropics/extratropics are defined as all points equatorward/poleward of 30° latitude.

991 The match between our analytic model and the kernel calculation implies that one can explain
 992 much of the spatial structure of λ_{LW} in terms of the analytic model's input parameters. We do
 993 this by calculating correlations between λ_{surf} and λ_{atm} from the kernel-derived feedback maps
 994 against the analytic model's five main inputs: surface temperature T_s , column relative humidity
 995 RH , stratospheric temperature T_{strat} , bulk lapse rate γ_{lr} , and the change in bulk lapse rate under

996 warming $d\gamma_{lr}/dT_s$. Spatial CO₂ contrasts are small (e.g., Fraser et al. 1983), and so do not need to
997 be considered here.

998 Figure 12 shows the resulting spatial correlations between the kernel-derived feedback maps
999 (left column of Figure 10) and the five inputs from HadGEM2 (Figure 9). Because the feedback
1000 maps differ strongly between tropics and extratropics in terms of zonal variation and magnitude,
1001 we compute correlations separately in these two regions (data are split based on being equatorward
1002 or poleward of 30° latitude). Based on the inherent correlations between the five input maps,
1003 we consider a correlation significant if its coefficient exceeds $|r| \geq 0.75$ (the largest intra-input
1004 correlations are $r = -0.71$ between T_s and T_{strat} in the tropics, and $r = -0.76$ between T_s and
1005 $d\gamma_{lr}/dT_s$ in the extratropics; not shown).

1006 In line with our analytic model, we find that the kernel-derived λ_{surf} is strongly correlated with
1007 column RH in the tropics ($r = 0.83$), while it does not show strong correlation with any inputs
1008 in the extratropics ($|r| < 0.4$). This underlines the importance of the subtropical dry radiator fin
1009 regions for λ_{surf} , which are clearly visible as the dark blue regions in Figure 9 (top right) and the
1010 yellow regions in Figure 10 (center left). As expected, the sign of the correlation is positive which
1011 means λ_{surf} becomes less negative, or less stabilizing, as column RH increases.

1012 Next, we find λ_{atm} is most strongly correlated with γ_{lr} and $d\gamma_{lr}/dT_s$ in the tropics ($r = 0.75$ for
1013 both), and with $d\gamma_{lr}/dT_s$ in the extratropics ($r = 0.88$). Of the two parameters that show strong
1014 correlations with λ_{atm} in the tropics, γ_{lr} and $d\gamma_{lr}/dT_s$, which one is more important? We performed
1015 a test with the analytical model in which we set $d\gamma_{lr}/dT_s = 0$ (not shown). Doing so eliminates most
1016 tropical structure in the map of λ_{atm} , which indicates that λ_{atm} is largely determined by $d\gamma_{lr}/dT_s$,
1017 not γ_{lr} . The correlation between λ_{atm} and $d\gamma_{lr}/dT_s$ is positive, which is intuitive: λ_{atm} becomes
1018 more negative if the upper atmosphere warms more relative to the surface, i.e. if γ_{lr} decreases. The
1019 spatial variability of λ_{atm} is largest in the tropics, and can be understood in terms of the map
1020 of $d\gamma_{lr}/dT_s$ already discussed in Section 6a: tropical λ_{atm} is large over subtropical eastern ocean
1021 basins due to suppressed surface warming, and small over land due to enhanced surface warming,
1022 where these warming patterns are relative to the approximately uniform warming of the tropical
1023 free troposphere (Byrne and O’Gorman 2013).

1024 The correlations shown in Figure 12 are between fields derived from two independent methods,
1025 and so are non-trivial. Appendix C shows that the same analysis performed with λ_{surf} and λ_{atm}

1026 from our analytic feedback maps identifies the same dominant relations (e.g., λ_{surf} is most strongly
1027 correlated with column RH in the tropics), though most correlation coefficients are unsurprisingly
1028 even larger (e.g., $r = 0.93$ for the analytic λ_{surf} and tropical column RH). Our results thus underline
1029 that the spatial pattern of λ_{LW} can be understood, at least in rough terms and on large spatial
1030 scales, by Earth’s spatial pattern of relative humidity and lapse rate changes. Relative humidity
1031 and lapse rate changes dominate the pattern of λ_{LW} in the tropics, where they control λ_{surf} and λ_{atm}
1032 respectively, while lapse rate changes dominate the pattern of λ_{atm} in the extratropics.

1033 7. Discussion & Conclusions

1034 In this paper we have presented a novel decomposition of Earth’s clear-sky longwave feedback
1035 λ_{LW} into four spectral components, namely a surface Planck feedback (λ_{surf}) and three atmospheric
1036 feedbacks: a CO₂ band feedback (λ_{CO_2}), a (non-Simpsonian) water vapor band feedback ($\lambda_{\text{H}_2\text{O}}$),
1037 and a destabilizing water vapor continuum feedback (λ_{cnt}). We have derived simple analytic
1038 expressions for each of these spectral feedbacks, which accurately reproduce the results of line-
1039 by-line calculations and qualitatively match the feedback map computed from a radiative kernel.
1040 In principle one could extend this approach even further to account for additional complicating
1041 factors, such as the effect of additional greenhouse gases or a more realistic stratosphere. However,
1042 our results already show that from a radiative perspective the factors determining λ_{LW} can be
1043 understood fairly easily, adding further support to the close agreement between observations and
1044 climate models.

1045 The picture of Earth’s clear-sky longwave feedback that emerges from this perspective is relatively
1046 simple, consisting of a surface feedback plus atmospheric feedbacks from CO₂ and H₂O. At present
1047 the surface feedback λ_{surf} is the most important contributor in the global-mean and at most latitudes,
1048 with its spatial pattern determined by the distribution of atmospheric water vapor. λ_{surf} is largest in
1049 the dry subtropics, consistent with the view that these are the locus of Earth’s stabilizing longwave
1050 feedback (Pierrehumbert 1995; McKim et al. 2021), and smallest in the inner tropics, where the
1051 surface’s emission is blocked by the H₂O continuum. The atmospheric feedbacks from the CO₂
1052 and H₂O bands play a supporting role to λ_{surf} at mid and high latitudes, but they rival the surface
1053 feedback in the inner tropics, with the global pattern of λ_{atm} largely determined by the pattern of
1054 the atmospheric lapse rate change $d\gamma_{\text{lr}}/dT_s$. The H₂O continuum provides a negligible feedback

1055 below ~ 310 K (see Section 5), but the continuum itself is still important through its influence on
1056 λ_{surf} .

1057 This spectral picture is arguably a more intuitive starting point for reasoning about different
1058 climates than the conventional decomposition of λ_{LW} into Planck, Lapse Rate and Water Vapor
1059 feedbacks. As discussed by Cronin and Dutta (in revision at QJRMS), it is non-trivial to accurately
1060 estimate the supposedly-simple Planck feedback from first principles. Similarly, one can qualita-
1061 tively reason that Lapse Rate and Water Vapor feedbacks both increase in magnitude under global
1062 warming, but these are large and of opposite sign, so it is difficult to predict their net change and, by
1063 extension, the T_s -dependence of λ_{LW} , in the conventional decomposition without resorting to nu-
1064 merical models. The strong cancellations between Planck, Lapse Rate and Water Vapor feedbacks
1065 can be alleviated by considering conventional feedbacks in a fixed relative humidity framework
1066 (Ingram 2010; Held and Shell 2012), but this comes at the cost that the state-dependence of the
1067 Planck feedback is no longer trivial to understand at fixed RH.

1068 In contrast, the state-dependence of λ_{LW} is fairly straightforward to understand from a spectral
1069 perspective, at least in broad brushstrokes. For present-day Earth the T_s -dependence of λ_{LW} is
1070 dominated by the surface in most regions. If relative humidity is fixed, λ_{surf} increases at very
1071 cold temperatures, peaks around 260 – 290 K depending on RH, and then decreases again (see
1072 Section 5). The decrease is rapid at high RH due to the H₂O continuum, but much slower at
1073 low RH. Atmospheric feedbacks also have state-dependence. All of them increase in magnitude
1074 as the atmosphere warms, and are further amplified by a weakening lapse rate. In the tropics
1075 the state-dependence of λ_{LW} is thus set by the interplay between a decreasing surface feedback
1076 and increasing atmospheric feedbacks. This can lead to surprising dynamics – at high RH, λ_{surf}
1077 decreases in magnitude more rapidly with warming than the atmospheric feedbacks from λ_{CO_2}
1078 and $\lambda_{\text{H}_2\text{O}}$ increase. As a result λ_{LW} becomes non-monotonic with warming and develops a local
1079 minimum around ~ 310 K, which leads to a local maximum in climate sensitivity (Seeley and
1080 Jeevanjee 2021).

1081 The state-dependence of λ_{LW} at temperatures far above ~ 310 K is beyond the scope of this
1082 paper, but a spectral perspective points to the importance of stabilizing H₂O and CO₂ bands versus
1083 the destabilizing H₂O continuum as Earth approaches the runaway greenhouse. The main caveat
1084 here is that Earth’s net feedback does not necessarily stay dominated by λ_{LW} at very high surface

1085 temperatures, and atmospheric feedbacks are also complicated at high temperatures by effects such
1086 as non-dilute thermodynamics and surface pressure changes (Goldblatt et al. 2013; Ramirez et al.
1087 2014).

1088 There are several remaining shortcomings in our analysis of λ_{LW} that are beyond the scope of
1089 this paper. A major one is our assumption that the atmosphere can be described by a single bulk
1090 lapse rate, such that temperature has to monotonically decrease with altitude. In the real world
1091 inversions are common, particularly in polar regions and over subtropical oceans. Comparable to
1092 the long-standing discussion about how to interpret the Lapse Rate feedback at high latitudes in
1093 the conventional decomposition (e.g., Cai and Lu 2009; Payne et al. 2015; Stuecker et al. 2018;
1094 Boeke et al. 2021; Henry et al. 2021), we therefore expect that our approach here only provides a
1095 first step towards understanding the processes which shape λ_{LW} in inversion regions.

1096 Another assumption is that we ignore stratospheric changes, even though stratospheric cooling
1097 induced by rising CO₂ levels is a major and robust signal of anthropogenic warming (e.g., Vallis
1098 et al. 2014). It is notable that the radiative changes due to stratospheric cooling are also hard
1099 to intuitively explain using conventional feedbacks. Climate model analyses typically treat the
1100 stratosphere's fast radiative adjustment to CO₂ changes as distinct from Planck, Lapse Rate, and
1101 Water Vapor feedbacks. Our derivations here sidestep this issue and treat T_{strat} as a fixed parameter.
1102 Similarly, our derivations ignore the potential feedback from relative humidity changes. In reality
1103 there is no guarantee that relative humidity will remain constant under global warming, let alone
1104 would have been similar in past climates. In principle our analysis starting from the emission level
1105 approximation can be extended to estimate the feedbacks associated with changes in either RH or
1106 T_{strat} ; RH changes would lead to a feedback term proportional to $\partial T_{\text{rad}}/\partial \text{RH}$, while stratospheric
1107 changes would lead to a feedback term proportional to $\partial T_{\text{rad}}/\partial T_{\text{strat}}$.

1111 *Data availability statement.* HadGEM2 GCM data is publicly available in CMIP data archives.
1112 The HadGEM2 radiative kernel is available at <https://archive.researchdata.leeds.ac.uk/382>.
1113 Scripts to compute analytic feedbacks will be posted online once the manuscript is
1114 accepted for publication.

APPENDIX A

CO₂ Forcing

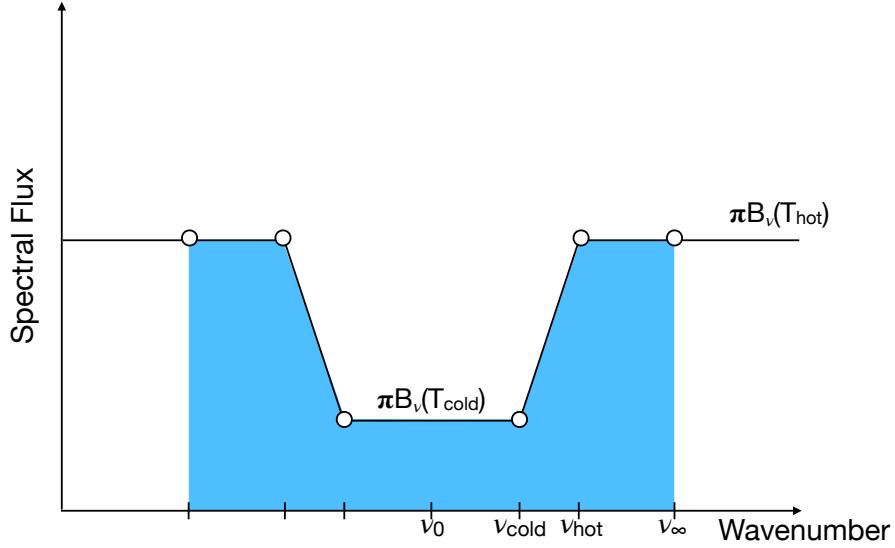

FIG. A1. CO₂ ditch model for the CO₂ forcing. The shaded blue area is the OLR contribution from the CO₂ band as well as neighboring spectral regions. The band edges ν_{hot} and ν_{cold} vary in response to CO₂ concentration q_{CO_2} , while ν_∞ is sufficiently far away from the CO₂ band to be constant with respect to q_{CO_2} .

The CO₂ ditch model can be used to explain the CO₂ forcing in addition to the CO₂ band feedback. This section rederives the CO₂ forcing expressions from Wilson and Gea-Banacloche (2012) and Jeevanjee et al. (2021b), which are valid as long as the CO₂ band center radiates from the stratosphere. Note that our CO₂ band feedback model only considers OLR changes inside the CO₂ band (see Figure 6). This is because the effect of CO₂ on $\lambda_{\text{H}_2\text{O}}$ or λ_{surf} is separately considered in the derivation of those feedbacks. Forcing is defined as the OLR change integrated across all wavenumbers, however, so here we need to consider the expanded shaded region shown in Figure A1. The OLR integrated across this expanded region, OLR_+ , is

$$\begin{aligned} \text{OLR}_+ &= 2 \int_{\nu_0}^{\nu_\infty} \pi B_{\nu_0}(T_{\text{rad}}) d\nu \\ &= \left[\pi B_{\nu_0}(T_{\text{hot}}) + \pi B_{\nu_0}(T_{\text{cold}}) \right] (\nu_{\text{hot}} - \nu_{\text{cold}}) + 2\pi B_{\nu_0}(T_{\text{cold}}) (\nu_{\text{cold}} - \nu_0) + \\ &\quad 2\pi B_{\nu_0}(T_{\text{hot}}) (\nu_\infty - \nu_{\text{hot}}). \end{aligned} \tag{A1}$$

1128 The forcing from a doubling of CO₂ is then

$$\begin{aligned}
F_{\text{CO}_2}^{2x} &= -\frac{d\text{OLR}_+}{d\log_2(q_{\text{CO}_2})} \\
&= -\ln(2)\frac{d\text{OLR}_+}{d\ln q_{\text{CO}_2}} \\
&= -\ln(2)\left(\left[\pi B_{\nu_0}(T_{\text{hot}}) + \pi B_{\nu_0}(T_{\text{cold}})\right]\left(\frac{d\nu_{\text{hot}}}{d\ln q_{\text{CO}_2}} - \frac{d\nu_{\text{cold}}}{d\ln q_{\text{CO}_2}}\right) + 2\pi B_{\nu_0}(T_{\text{cold}})\frac{d\nu_{\text{cold}}}{d\ln q_{\text{CO}_2}} - \right. \\
&\quad \left. 2\pi B_{\nu_0}(T_{\text{hot}})\frac{d\nu_{\text{hot}}}{d\ln q_{\text{CO}_2}}\right) \tag{A2}
\end{aligned}$$

1129 The minus sign in the first line ensures that forcing is positive when OLR decreases, while the
1130 base-2 logarithm is necessary because forcing is defined with respect to a CO₂ doubling. In the
1131 second step we then change the logarithm's base to the natural logarithm, while in the third step
1132 we treat the emission temperatures T_{hot} and T_{cold} as constant. This is valid because the derivative
1133 of OLR with respect to q_{CO_2} is taken at fixed T_s (i.e., at fixed surface temperature, the temperature
1134 outside the CO₂ band and in the stratosphere are both independent of CO₂ concentration).

1135 The CO₂ band edges are defined by $T_{\text{CO}_2}(\nu_{\text{hot}}) = T_{\text{hot}}$ and $T_{\text{CO}_2}(\nu_{\text{cold}}) = T_{\text{strat}}$. Solving for ν_{hot} and
1136 ν_{cold} we find

$$\nu_{\text{hot}} = \nu_0 + l_\nu \log \left[q_{\text{CO}_2} \tau_{\text{CO}_2}^*(\nu_0) \left(\frac{T_{\text{hot}}}{T_s} \right)^{2/\gamma_{\text{lr}}} \right] \tag{A3}$$

$$\nu_{\text{cold}} = \nu_0 + l_\nu \log \left[q_{\text{CO}_2} \tau_{\text{CO}_2}^*(\nu_0) \left(\frac{T_{\text{strat}}}{T_s} \right)^{2/\gamma_{\text{lr}}} \right]. \tag{A4}$$

1137 We can see that the CO₂ band edges shift equally in response to a CO₂ increase:

$$\frac{d\nu_{\text{hot}}}{d\ln q_{\text{CO}_2}} = \frac{d\nu_{\text{cold}}}{d\ln q_{\text{CO}_2}} = l_\nu. \tag{A5}$$

1138 It follows that the first term proportional to $d\nu_{\text{hot}}/d\ln q_{\text{CO}_2} - d\nu_{\text{cold}}/d\ln q_{\text{CO}_2}$ in Equation A2 is zero.

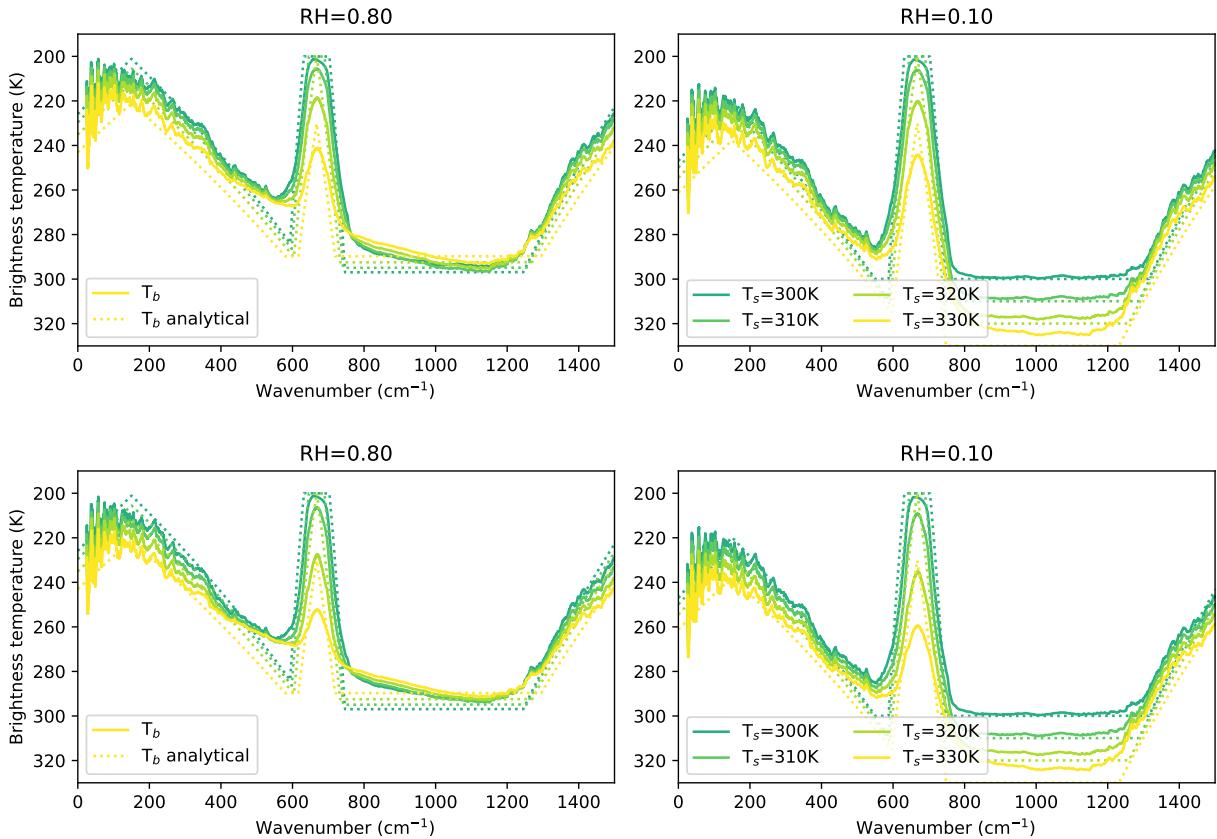

1139 The CO₂ forcing is thus

$$F_{\text{CO}_2}^{2x} = 2\ln(2)l_\nu (\pi B_{\nu_0}(T_{\text{hot}}) - \pi B_{\nu_0}(T_{\text{cold}})), \tag{A6}$$

1140 which is identical to the analytic CO₂ forcing model in Jeevanjee et al. (2021b) (their Equations 7
 1141 and 14).

1142 APPENDIX B

1143 Transition from stratospheric to tropospheric CO₂ radiator fin

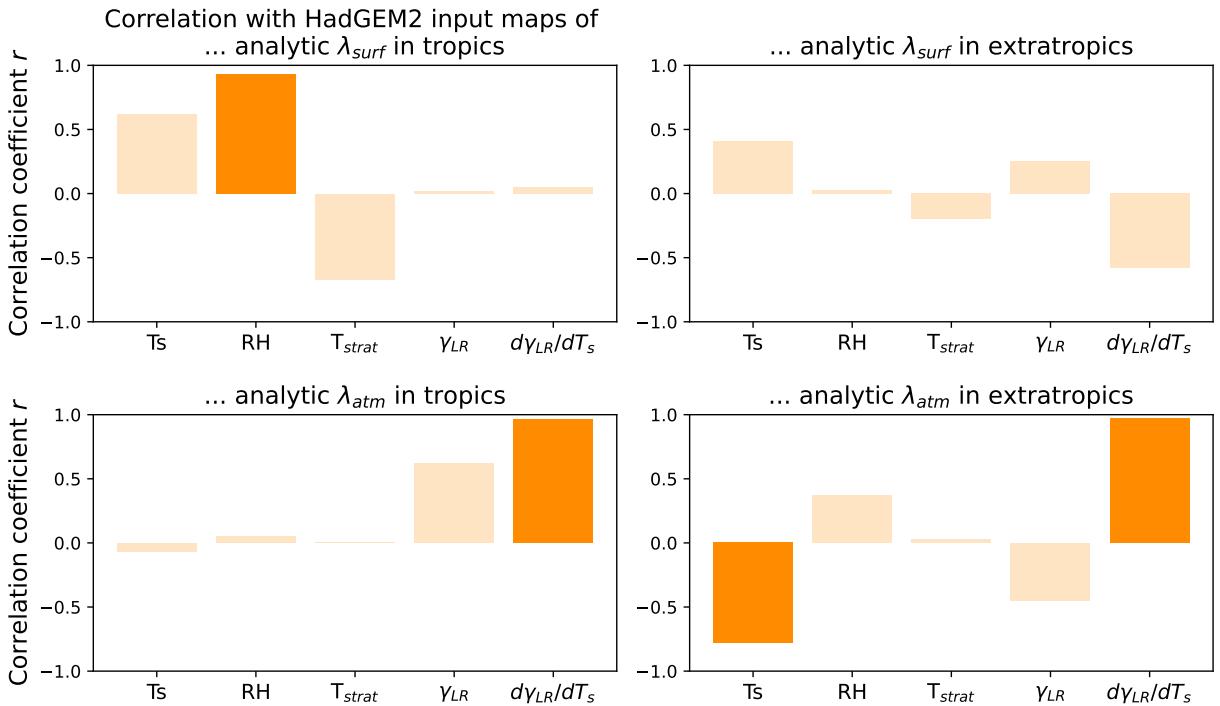

1144 FIG. B1. Brightness temperatures computed from line-by-line calculations and smoothed with a 50 cm⁻¹
 1145 median filter (solid), versus analytic emission temperatures (dashed). Top row: calculations use a bulk lapse-rate
 1146 profile, $T(p) = T_s(p/p_s)^{\gamma_r}$. Bottom row: calculations use a moist adiabat.

1147 At high surface temperatures the CO₂ band center transitions from mainly radiating from the
 1148 stratosphere to mainly radiating from the troposphere. Figure B1 shows smoothed brightness
 1149 temperatures T_b computed from the 1D line-by-line calculations described in Section 5, with a
 1150 CO₂ volume-mixing ratio of 400 ppm. In the middle of the CO₂ band, at about 667 cm⁻¹, CO₂
 1151 radiates from the troposphere at surface temperatures above ~ 310 K. In rough agreement with

1152 the line-by-line results, our analytic CO₂ brightness temperatures predict this transition happens
 1153 at a surface temperature of ~ 320 K (dashed lines in Fig. B1). In practice we therefore use a
 1154 transition temperature of $T_{s,0} = 310$ K for 400 ppm of CO₂ to determine when CO₂ changes from
 1155 a stratospheric to a tropospheric radiator.

1156 APPENDIX C

1157 Spatial correlations in analytic feedback maps

1158 FIG. C1. Spatial correlation between the analytic feedback maps of λ_{surf} and λ_{atm} (Figure 10, right column),
 1159 and the inputs to our analytic model (Figure 9). Top row shows correlations between inputs and λ_{surf} , bottom row
 1160 shows correlations between inputs and λ_{atm} . Left column shows correlations inside the tropics, right column
 1161 shows correlations in the extratropics. Dark colors highlight particularly strong correlations ($|r| \geq 0.8$).

1162 Figure C1 repeats the same analysis as in Figure 12, but using the analytic feedback maps of
 1163 λ_{surf} and λ_{atm} . Given that the analytic λ model is computed using the input fields from Figure 9, it
 1164 is not surprising that most correlations between inputs and feedback maps are even higher than in
 1165 Fig. 12. With the exception of λ_{atm} in the tropics, for which the correlation between the analytic

1166 λ_{atm} and γ_{lr} is slightly lower than between kernel-derived λ_{atm} and γ_{lr} , Figure C1 identifies the
1167 same strong correlations as Figure 12.
